Abstract

The American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) convened a writing group to develop a consensus statement on the management of type 1 diabetes in adults. The writing group has considered the rapid development of new treatments and technologies and addressed the following topics: diagnosis, aims of management, schedule of care, diabetes self-management education and support, glucose monitoring, insulin therapy, hypoglycaemia, behavioural considerations, psychosocial care, diabetic ketoacidosis, pancreas and islet transplantation, adjunctive therapies, special populations, inpatient management and future perspectives. Although we discuss the schedule for follow-up examinations and testing, we have not included the evaluation and treatment of the chronic microvascular and macrovascular complications of diabetes as these are well-reviewed and discussed elsewhere. The writing group was aware of both national and international guidance on type 1 diabetes and did not seek to replicate this but rather aimed to highlight the major areas that healthcare professionals should consider when managing adults with type 1 diabetes. Though evidence-based where possible, the recommendations in the report represent the consensus opinion of the authors.

Keywords Adjunctive therapy · Diabetic ketoacidosis · Diagnosis · Exercise · Glucose monitoring · Hypoglycaemia · Insulin · Nutrition · Psychosocial care · Schedule of care · Transplantation · Type 1 diabetes

Abbreviations

App Application
BGAT Blood glucose awareness training
BGM Blood glucose monitoring

CGM Continuous glucose monitoring
COVID-19 Coronavirus disease-2019
DKA Diabetic ketoacidosis
DSMES Diabetes self-management education and support
EDIC Epidemiology of Diabetes Interventions and Complications
FDA US Food and Drug Administration
GLP-1 RA Glucagon like peptide-1 receptor agonists
GMI Glucose management indicator
IAH Impaired awareness of hypoglycaemia
is-CGM Intermittently scanned continuous glucose monitoring
MDI Multiple daily injections
PTA Pancreas transplants alone
rt-CGM Real-time continuous glucose monitoring
SGLT Sodium–glucose cotransporter
SPK Simultaneous pancreas and kidney
TBR Time below range
TIR Time in range

This Consensus Report is jointly published in *Diabetologia*, published by Springer-Verlag, GmbH, on behalf of the European Association for the Study of Diabetes <https://doi.org/10.1007/s00125-021-05568-3>; and *Diabetes Care*, published by the American Diabetes Association <https://doi.org/10.2337/DCi21-0043>.

A consensus report of a particular topic contains a comprehensive examination and is authored by an expert panel and represents the panel's collective analysis, evaluation, and opinion. The article was reviewed for EASD by its Committee on Clinical Affairs and approved by its Executive Board and for ADA by its Professional Practice Committee.

Section 1: Introduction and rationale for the consensus report

Type 1 diabetes is a condition caused by autoimmune damage of the insulin-producing beta cells of the pancreatic islets, usually leading to severe endogenous insulin deficiency. Type 1 diabetes accounts for approximately 5–10% of all cases of diabetes. Although the incidence peaks in puberty and early adulthood, new-onset type 1 diabetes occurs in all age groups and people with type 1 diabetes live for many decades after onset of the disease, such that the overall prevalence of type 1 diabetes is higher in adults than in children, justifying our focus on type 1 diabetes in adults [1]. The global prevalence of type 1 diabetes is 5.9 per 10,000 people, while the incidence has risen rapidly over the last 50 years and is currently estimated to be 15 per 100,000 people per year [2].

Prior to the discovery of insulin a century ago, type 1 diabetes was associated with a life expectancy as short as a few months. Beginning in 1922, relatively crude extracts of exogenous insulin, derived from animal pancreases, were used to treat people with type 1 diabetes. Over the ensuing decades, insulin concentrations were standardised, insulin solutions became more pure, resulting in reduced immunogenicity, and additives, such as zinc and protamine, were incorporated into insulin solutions to increase the duration of action. In the 1980s, semi-synthetic and recombinant human insulins were developed and in the mid 1990s, insulin analogues became available. Basal insulin analogues were designed with prolonged duration of action and reduced pharmacodynamic variability compared with protamine-based (NPH) human insulin, while rapid-acting analogues were introduced with quicker onset and shorter duration than short-acting ('regular') human insulin, resulting in reduced early postprandial hyperglycaemia and less later hypoglycaemia several hours after the meal [3].

The discovery of insulin transformed the lives of many people, but it soon became apparent that type 1 diabetes is associated with the development of long-term complications and shortened life expectancy. Over the last 100 years, developments in insulin, its delivery, and technologies to measure glycaemic indices have markedly changed the management of type 1 diabetes. Despite these advances, many people with type 1 diabetes do not reach the glycaemic targets necessary to prevent or slow the progression of diabetes complications, which continue to exert a high clinical and emotional burden.

Recognising the ongoing challenge of type 1 diabetes and the rapid development of new treatments and technologies, the European Association for the Study of Diabetes (EASD) and the American Diabetes Association (ADA) convened a writing group to develop a consensus report on the management of type 1 diabetes in adults, aged 18 years and over. The writing group was aware of both national and international guidance on type 1 diabetes and did not seek to replicate this, but rather aimed to

highlight the major areas of care that healthcare professionals should consider when managing adults with type 1 diabetes. The consensus report has focused predominantly on current and future glycaemic management strategies and metabolic emergencies. Recent advances in the diagnosis of type 1 diabetes have been considered. Unlike many other chronic conditions, type 1 diabetes places a unique burden of management on the individual with the condition. In addition to complex medication regimens, other behavioural modification is also needed; all of this requires considerable knowledge and skill to navigate between hyper- and hypoglycaemia. The importance of diabetes self-management education and support (DSMES) and psychosocial care are rightly documented in the report. While acknowledging the major significance and cost of screening, diagnosing and managing the chronic microvascular and macrovascular complications of diabetes, a detailed description of the management of these complications is beyond the scope of this report.

Two members of the writing group, one from the ADA and one from the EASD, were assigned to be the primary authors of each section. The chosen individuals had specific knowledge of the area and were tasked with reviewing and summarising the available literature. Each section, in turn, was reviewed and approved by the entire writing group. The draft consensus report was peer reviewed (see the Acknowledgements section) and suggestions were incorporated as deemed appropriate by the authors. The revised draft report was presented at the virtual ADA Scientific Sessions in 2021, after which public comments were invited. The report was further revised in light of this consultation. Large areas of clinical practice in type 1 diabetes are based on expert opinion and cohort studies rather than RCTs and so the writing group considered both observational and clinical trial findings, rather than relying solely on unbiased RCTs and meta-analyses. The report represents the consensus opinion of the authors, given that the available evidence is incomplete.

Section 2: Diagnosis of type 1 diabetes

Adults with new-onset type 1 diabetes can present with a short duration of illness of 1–4 weeks or a more slowly evolving process that can be mistaken for type 2 diabetes. Several other types of diabetes, for example monogenic diabetes, can be misdiagnosed as type 1 diabetes. In older adults, pancreatic cancer may present with diabetes and weight loss. A new and emerging issue is the development of profound insulin deficiency associated with the use of immune check-point inhibitors, which may present with hyperglycaemia and diabetic ketoacidosis (DKA) [4].

Most of the available data discussed below are derived from White European populations and may not be representative of other ethnic groups. The clinical presentation may differ, but the classical triad of thirst and polydipsia, polyuria and weight loss are common symptoms of type 1 diabetes. Accurate classifica-

tion of the type of diabetes has implications beyond the use of insulin treatment; education, insulin regimen, use of adjuvant therapies, access to newer technologies, need for psychosocial support to address the profound psychological impact of the diagnosis of diabetes and concurrent disease screening may all depend on the diagnosis an individual receives. Furthermore, accurate diagnosis allows an assessment of the risk of diabetes in first-degree relatives and appropriate counselling. Although profound insulin deficiency is the hallmark of type 1 diabetes, some adults with type 1 diabetes maintain some insulin secretion for years after diagnosis and may not require insulin treatment at diagnosis [5], leading to diagnostic uncertainty about the type of diabetes and its management.

Differentiating type 1 diabetes from type 2 diabetes

Identifying whether an adult with newly diagnosed diabetes has type 1 diabetes may be challenging where the individual has features pointing towards both type 1 diabetes and type 2 diabetes, such as an older adult with a low or normal BMI or young adult with an elevated BMI. Ketoacidosis, once considered pathognomonic of type 1 diabetes, may occur in ketosis-prone type 2 diabetes. Misclassification of type 1 diabetes in adults is common and over 40% of those developing type 1 diabetes after age 30 years are initially treated as having type 2 diabetes [6–8]. From a patient perspective, a misdiagnosis of type 2 diabetes can cause confusion and misunderstanding, especially for those with type 1 diabetes who have overweight or obesity. This can impair the acceptance of the diagnosis and future management plans. No single clinical feature confirms type 1 diabetes in isolation [9, 10]. The most discriminative feature is younger age at diagnosis (<35 years), with lower BMI (<25 kg/m²), unintentional weight loss, ketoacidosis and glucose >20 mmol/l (>360 mg/dl) at presentation also being informative. Other features classically associated with type 1 diabetes, such as ketosis without acidosis, osmotic symptoms, family history or a history of autoimmune diseases are weak discriminators [8–10].

The very strong relationship between type 2 diabetes incidence and age means that even ‘classical’ features of type 1 diabetes may have a limited predictive value in older adults, as type 2 diabetes in this age group is so common [11]. The majority of older adults with low BMI will have type 2 diabetes [9, 12, 13], even more so when a person’s ethnicity is associated with high type 2 diabetes risk [14]. Rapid progression to insulin treatment (<3 years) is strongly suggestive of type 1 diabetes at any age [6, 8, 15]. The diagnosis of type 1 diabetes can be more difficult in adults who progress to insulin therapy more slowly. Controversy remains as to whether latent autoimmune diabetes of adulthood (LADA) is a discrete subtype, a milder form of type 1 diabetes, or a mixture of some individuals with type 1 diabetes and others with type 2 diabetes [16, 17].

Differentiating type 1 diabetes from monogenic diabetes

Monogenic diabetes is found in approximately 4% of those diagnosed with diabetes before the age of 30 years; the likelihood of monogenic diabetes rises to 20% where islet antibodies are negative and C-peptide secretion is maintained [18]. Monogenic diabetes is commonly mistaken for type 1 diabetes because of the young age at onset. A diagnosis of monogenic diabetes allows specific treatment with discontinuation of insulin in many cases and has implications for family members and screening for concurrent conditions [19, 20].

Investigation of an adult with suspected type 1 diabetes

An algorithm for the investigation of adults with suspected type 1 diabetes is shown in Fig. 1.

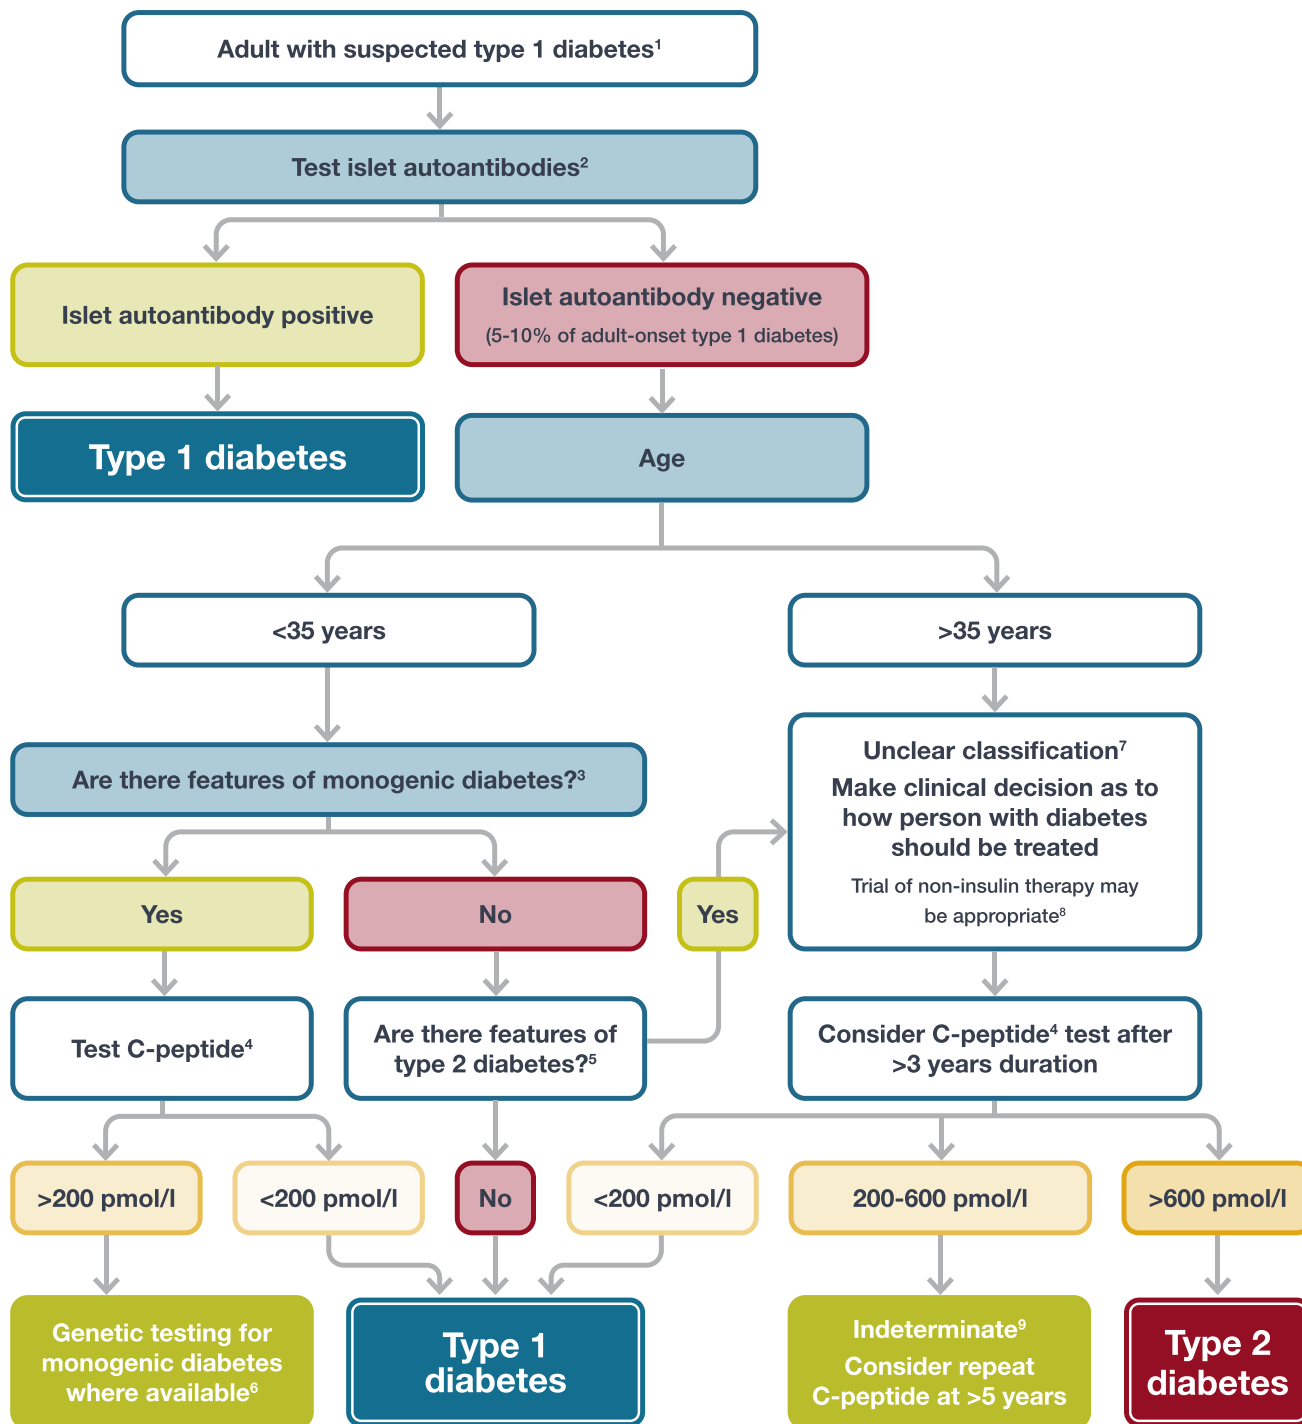

Islet autoantibodies An assessment of islet autoantibodies at diagnosis is recommended as the primary investigation of an adult with suspected type 1 diabetes. GAD should be the primary antibody measured and, if negative, should be followed by islet tyrosine phosphatase 2 (IA2) and/or zinc transporter 8 (ZNT8) where these tests are available. Islet cell antibody (ICA) measurement is no longer recommended because it is an imprecise biological assay that has been superseded by the direct measurement of single antibodies [21, 22].

In people with clinical features suggesting type 1 diabetes, the presence of one or more positive islet autoantibodies is highly predictive of rapid progression and severe insulin deficiency and these individuals should be considered to have type 1 diabetes, even if they did not require insulin at diagnosis [23, 24]. As positive GAD antibodies may be found at a low level in adults without autoimmune diabetes and false positive results may occur, GAD should only be measured in those suspected to have type 1 diabetes [24].

The absence of autoantibodies does not exclude type 1 diabetes, since approximately 5–10% of White European people with new-onset type 1 diabetes have negative islet antibodies [8, 9, 25], and further consideration of the diagnosis is necessary. Furthermore, antibodies may disappear over time [26]. In those diagnosed below the age of 35 years, type 1 diabetes is still the most likely diagnosis, particularly if there are no clinical features of type 2 diabetes or monogenic diabetes. In those aged over 35 years, type 2 diabetes becomes increasingly likely with absent islet autoantibodies and older age. However, it can be hard to differentiate between type 1 diabetes and type 2 diabetes based on age and clinical features in non-White European populations.

It is important to make a clinical decision about how to treat the person with diabetes. Regardless of any features of type 2 diabetes or absence of islet antibodies, if there is a clinical suspicion of type 1 diabetes, the individual should be treated with

Flow chart for investigation of suspected type 1 diabetes in newly diagnosed adults, based on data from White European populations

insulin. However, in some individuals, where the clinical course is more suggestive of type 2 diabetes, a trial of non-insulin therapy may be appropriate. Those whose diabetes is treated without insulin will require careful monitoring and education so that insulin can

be rapidly initiated in the event of glycaemic deterioration. Type 2 diabetes and other types of diabetes should be considered in all age groups, but in those aged under 35 years, negative islet antibodies should raise the suspicion of monogenic diabetes.

◀ **Fig. 1** Flow chart for investigation of suspected type 1 diabetes in newly diagnosed adults, based on data from White European populations. ¹No single clinical feature confirms type 1 diabetes in isolation. The most discriminative feature is younger age at diagnosis (<35 years), with lower BMI (<25 kg/m²), unintentional weight loss, ketoacidosis, and glucose >20 mmol/l (>360 mg/dl) at presentation also being informative. Other features classically associated with type 1 diabetes, such as ketosis without acidosis, osmotic symptoms, family history or a history of autoimmune diseases are weak discriminators. ²GAD should be the primary antibody measured and, if negative, should be followed by islet tyrosine phosphatase 2 (IA2) and/or zinc transporter 8 (ZNT8) where these tests are available. In those diagnosed below the age of 35 years who have no clinical features of type 2 diabetes or monogenic diabetes, a negative result does not change the diagnosis of type 1 diabetes since 5–10% of people with type 1 diabetes do not have antibodies. ³Monogenic diabetes is suggested by the presence of one or more of the following features: HbA_{1c} <58 mmol/mol (7.5%) at diagnosis, one parent with diabetes, features of specific monogenic cause (e.g. renal cysts, partial lipodystrophy, maternally inherited deafness, severe insulin resistance in the absence of obesity), and monogenic diabetes prediction model probability >5% (www.diabetesgenes.org/exeter-diabetes-app/ModyCalculator; accessed 20 August 2021). ⁴A C-peptide test is only indicated in people receiving insulin treatment. A random sample (with concurrent glucose) within 5 h of eating can replace a formal C-peptide stimulation test in the context of classification. If the result is ≥600 pmol/l, the circumstances of testing do not matter. If the result is <600 pmol/l and the concurrent glucose is <4 mmol/l (<72 mg/dl) or the person may have been fasting, consider repeating the test. Results showing very low levels (<80 pmol/l) do not need to be repeated. Where a person is insulin-treated, C-peptide must be measured prior to insulin discontinuation to exclude severe insulin deficiency. Do not test C-peptide within 2 weeks of a hyperglycaemic emergency. ⁵Features of type 2 diabetes include increased BMI (≥25 kg/m²), absence of weight loss, absence of ketoacidosis and less marked hyperglycaemia. Less discriminatory features include non-White ethnicity, family history, longer duration and milder severity of symptoms prior to presentation, features of the metabolic syndrome and absence of a family history of autoimmunity. ⁶If genetic testing does not confirm monogenic diabetes, the classification is unclear and a clinical decision should be made about treatment. ⁷Type 2 diabetes should be strongly considered in older individuals. In some cases, investigation for pancreatic or other types of diabetes may be appropriate. ⁸A person with possible type 1 diabetes who is not treated with insulin will require careful monitoring and education so that insulin can be rapidly initiated in the event of glycaemic deterioration. ⁹C-peptide values 200–600 pmol/l are usually consistent with type 1 diabetes or maturity-onset diabetes of the young (MODY) but may occur in insulin-treated type 2 diabetes, particularly in people with normal or low BMI or after long duration

C-peptide measurement Beyond 3 years after diagnosis where there is uncertainty about diabetes type, a random C-peptide measurement (with concurrent glucose) within 5 h of eating is recommended. Where a person is treated with insulin, this test should always be performed prior to insulin discontinuation to exclude severe insulin deficiency.

Persistent C-peptide >600 pmol/l (non-fasting) is strongly suggestive of type 2 diabetes and people with C-peptide in this range are often able to replace insulin with other agents [27–30]. Routine C-peptide testing in those with clinically diagnosed type 1 diabetes of at least 3 years duration has led to reclassification in 11% of those with adult-onset diabetes

[31]. By contrast, low or absent C-peptide confirms the diagnosis of type 1 diabetes. Although low C-peptide concentrations may occur in some types of secondary diabetes and very long-standing type 2 diabetes, these situations are unlikely to be confused for type 1 diabetes; however, in some cases, investigation of other types of diabetes may be appropriate.

Plasma C-peptide is the recommended test where available, with modestly higher performance than urine measurement. The latter may be confounded by impaired renal function. If urinary C-peptide:creatinine ratio is used, a value <0.2 nmol/mol can be used to define severe insulin deficiency.

Genetic testing As monogenic diabetes was less likely to have been considered in the past, molecular genetic testing for neonatal diabetes should be considered for all people with type 1 diabetes, regardless of current age, who were diagnosed under 6 months of age as more than 80% have monogenic neonatal diabetes, and the 30–50% with ATP-sensitive potassium (K_{ATP}) channel mutations can replace insulin with sulfonylureas [32, 33].

Monogenic diabetes should be considered in those with one or more of the following features: age at diagnosis of less than 35 years, HbA_{1c} <58 mmol/mol (7.5%) at diagnosis, one parent with diabetes, and features of specific monogenic cause (e.g. renal cysts, partial lipodystrophy, maternally inherited deafness, severe insulin resistance in the absence of obesity) [34]. A monogenic diabetes prediction model risk calculator (www.diabetesgenes.org/mody-probability-calculator; accessed 20 August 2021) may also be used to identify which individuals diagnosed between 6 months and 35 years are at increased risk of monogenic diabetes [35]. Those at increased risk should have islet autoantibody and C-peptide testing. Molecular genetic testing should only be considered if the antibodies are negative and non-fasting C-peptide is >200 pmol/l [36–38]. Molecular genetic testing is not universally available.

Section 3: Aims and goals of management of type 1 diabetes

The aim of diabetes care and management is to support people with type 1 diabetes to live a long and healthy life. The management strategies to achieve this aim broadly include:

- Effectively delivering exogenous insulin to maintain glucose levels as close to the individual's target range as is safely possible to prevent the development and progression of diabetes complications while:
 - Minimising episodes of hypoglycaemia, of all levels, including Level 1 (<3.9 to ≥3.0 mmol/l [<70 to ≥ 54 mg/dl]) but, in particular, Level 2 (<3.0 mmol/l [<54 mg/dl]) and Level 3 (severe

event characterised by altered mental and/or physical functioning that requires assistance from another person for recovery) hypoglycaemia, and preventing episodes of DKA, while treating these appropriately should they occur.

- Effectively managing cardiovascular risk factors.
- Providing approaches, treatments and devices that minimise the psychosocial burden of living with type 1 diabetes and, consequently, diabetes-related distress, while promoting psychological wellbeing.

Management strategies should adapt to new therapies and technologies as they become available, according to the wishes and desires of the person with diabetes.

The importance of glycaemic management was demonstrated convincingly by the DCCT [39] and the Epidemiology of Diabetes Interventions and Complications (EDIC) follow-up study [40]. With the use of intensive insulin therapy that aimed to achieve blood glucose levels close to the non-diabetes range, HbA_{1c} was lowered by ~2% (22 mmol/mol) to a mean HbA_{1c} of ~7.0% (53 mmol/mol) over a mean of 6.5 years, compared with standard care (mean HbA_{1c} ~9.0% [75 mmol/mol]) [39]. The risk of primary development of retinopathy was reduced by 75% and progression of retinopathy slowed by 54%. The development of microalbuminuria was reduced by 39% and clinical neuropathy by 60% in those assigned to intensive therapy. These benefits persisted beyond the end of the trial despite equivalent glucose levels in the two groups (HbA_{1c} ~8% [64 mmol/mol]) in the post-trial period; furthermore, reductions in incident cardiovascular disease and mortality in the intensively-treated group emerged with time [40]. This seminal study has been the basis for glycaemic target recommendations for type 1 diabetes worldwide. The cost of intensive management was, however, a 2–3-fold increase in the rates of severe hypoglycaemia, as well as weight gain.

The main results of the DCCT were published in 1993, before any of the current insulin analogues and diabetes technologies, except for insulin pumps, were available. Increasingly, achieving and maintaining glucose levels in the target range have become possible with fewer episodes of hypoglycaemia [41–44]. Although the evidence of HbA_{1c} reduction remains the most robust measure associated with chronic diabetes complications and is the only measure that is prospectively validated, more recent studies have begun to examine the relationship between time that glucose is within the target range and long-term complications and have provided the basis for glycaemic targets with newer glucose monitoring technologies [45, 46].

The glycaemic target should be individualised considering factors that include duration of diabetes, age and life expectancy, comorbid conditions, known cardiovascular disease or advanced microvascular complications, impaired awareness

of hypoglycaemia (IAH) and other individual considerations, and it may change over time. Goals should be achieved in conjunction with an understanding of the person's psychosocial needs and a reduction in diabetes distress if elevated. An HbA_{1c} goal for most adults of <53 mmol/mol (<7.0%) without significant hypoglycaemia is appropriate. Following discussion between the person with diabetes and their healthcare team, achievement of lower HbA_{1c} levels than the goal of 53 mmol/mol (7%) may be acceptable, and even beneficial, if these can be achieved safely without adverse effects of treatment. Less-stringent HbA_{1c} goals (such as <64 mmol/mol [<8.0%]) may be appropriate for individuals with limited life expectancy or where the harms of treatment are greater than the benefits. It should be recognised that any reduction in HbA_{1c} from high initial levels has significant benefit even if the 'goal' is not reached.

Capillary blood glucose monitoring (BGM) can help people with type 1 diabetes achieve these HbA_{1c} goals. A preprandial capillary plasma glucose target of 4.4–7.2 mmol/l (80–130 mg/dl) is appropriate for many people. Postprandial glucose may be targeted if HbA_{1c} goals are not met despite reaching preprandial glucose targets. Postprandial glucose measurements should be made 1–2 h after the beginning of the meal, which generally corresponds to peak levels in people with diabetes. A peak postprandial capillary plasma glucose of <10.0 mmol/l (<180 mg/dl) is appropriate for most people with diabetes, although an ideal target for normoglycaemia is <7.8 mmol/l (<140 mg/dl). Higher goals in those with limited life expectancy or where the harms of treatment are greater than the benefits are recommended (Table 1).

Further measurements that complement HbA_{1c} and BGM are assessments of the glucose management indicator (GMI) and time in range (TIR) from continuous glucose monitoring (CGM) data. GMI is calculated based on the average sensor glucose over the last 14 days and provides an approximation of a laboratory-measured HbA_{1c} in some individuals, but it may be higher or lower than actual HbA_{1c} in others [45]. GMI and TIR may be more useful than HbA_{1c} for clinical management because they reflect more recent blood glucose levels and provide more detailed clinical information. A typical GMI goal is <53 mmol/mol (<7.0%). TIR is often taken as 3.9–10 mmol/l (70–180 mg/dl) for most adults and time below range (TBR) as below 3.9 mmol/l (70 mg/dl) (risk alert level), as well as less than 3.0 mmol/l (54 mg/dl) (clinically significant). Other metrics are also defined (Fig. 2). TIR is associated with microvascular complications [45, 46] and a TIR of 70% roughly corresponds to an HbA_{1c} of 53 mmol/mol (7.0%). An international consensus conference reported that for most adults with type 1 diabetes, a target TIR should be above 70%, with TBR less than 4% and less than 1% for clinically significant hypoglycaemia. The primary target for older people with a long duration of diabetes should be TBR less than 1% [47].

Table 1 Glycaemic targets for most adults with type 1 diabetes

Variable	Target value
HbA _{1c}	<53 mmol/mol (<7.0%)
GMI	<53 mmol/mol (<7.0%)
Preprandial glucose	4.4–7.2 mmol/l (80–130 mg/dl)
1–2 h postprandial glucose ^a	<10.0 mmol/l (<180 mg/dl)
TIR	>70%
TBR	
Readings and time <3.9 mmol/l (<70 mg/dl; Level 1 and Level 2 hypoglycaemia) ^b	<4%
Readings and time <3.0 mmol/l (<54 mg/dl; Level 2 hypoglycaemia) ^b	<1%
Time above range	
Readings and time >10.0 mmol/l (>180 mg/dl; Level 1 and Level 2 hyperglycaemia) ^c	<25%
Readings and time >13.9 mmol/l (>250 mg/dl; Level 2 hyperglycaemia) ^c	<5%
Glycaemic variability (%CV) ^d	≤36%

All glycaemic targets should be individualised and agreed with the person with diabetes. Lower or higher targets may be appropriate according to individual characteristics

^a A postprandial glucose target of <7.8 mmol/l (<140 mg/dl) may be recommended if this can be achieved safely. Higher targets in those with limited life expectancy or where the harms of treatment are greater than the benefits are recommended. In some individuals at notably higher risk for Level 3 hypoglycaemia, it may be necessary to increase the glucose target range to decrease the TBR

^b Level 1 hypoglycaemia is defined as blood glucose levels <3.9 to ≥3.0 mmol/l (<70 to ≥54 mg/dl); Level 2 hypoglycaemia is defined as blood glucose levels <3.0 mmol/l (<54 mg/dl)

^c Level 1 hyperglycaemia is defined as blood glucose levels >10.0 to ≤13.9 mmol/l (>180 to ≤250 mg/dl); Level 2 hyperglycaemia is defined as blood glucose levels >13.9 mmol/l (>250 mg/dl)

^d Some studies suggest that lower %CV targets (<33%) provide additional protection against hypoglycaemia

The cornerstone of type 1 diabetes therapy is insulin replacement. This is challenging because insulin demands vary widely according to meals, exercise and many other factors. Furthermore, the insulin doses needed to prevent hyperglycaemia are associated with a high risk of hypoglycaemia, leaving people with type 1 diabetes walking a tightrope between high and low glucose levels. Insulin management must be supported by adequate monitoring of glucose and education and training to allow the individual with type 1 diabetes to make the most of their treatment regimen.

The prevention of long-term complications of diabetes, particularly cardiovascular disease, extends beyond glycaemic management to include the optimal management of blood pressure and use of lipid-lowering

medication. There is an absence of high-quality data to guide blood pressure targets in type 1 diabetes, but RCTs in other populations have demonstrated that treatment of hypertension to a blood pressure <140/90 mmHg reduces cardiovascular events and microvascular complications. Blood pressure targets should be individualised but a target of <140/90 mmHg is appropriate for those with a lower risk for cardiovascular disease (10 year risk of <15%). A lower target of <130/80 mmHg is recommended for those at higher cardiovascular disease risk or with evidence of microvascular complications, particularly renal disease. ACE inhibitors or angiotensin receptor blockers are recommended first-line therapies.

Similar to the situation for blood pressure, there is a paucity of trials of lipid-lowering therapy in people with type 1 diabetes, but an observational study reported that lipid-lowering therapy is associated with a 22–44% reduction in the risk of cardiovascular disease and death among individuals with type 1 diabetes without a prior history of cardiovascular disease [48]. Based on type 2 diabetes guidelines, moderate-intensity statins should be considered for people aged over 40 years, and in those aged between 20–39 years with additional atherosclerotic cardiovascular disease risk factors or when the 10 year cardiovascular risk estimated by one of the risk calculators suitable for people with type 1 diabetes exceeds 10% [49–51]. Additional agents, such as ezetimibe or proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors, may be needed.

Antiplatelet agents, such as aspirin, should be considered for all people with type 1 diabetes and existing cardiovascular disease. Antiplatelet agents may be indicated for primary prevention but the benefit should be balanced with the increased risk of gastrointestinal bleeding.

In asymptomatic people with type 1 diabetes, routine screening for coronary artery disease is not recommended as it does not improve outcomes as long as atherosclerotic cardiovascular disease risk factors are treated. However, investigations for coronary artery disease should be considered if the person has any of the following: atypical cardiac symptoms, signs or symptoms of associated vascular disease or electrocardiogram abnormalities.

Type 1 diabetes is a demanding condition and requires ongoing professional medical, educational and psychosocial support. Care may differ at particular times of life, such as at the point of diagnosis, during concomitant illness or pregnancy, and later in life. Given the complexity of management, healthcare professionals should have the appropriate skills, training and resources to help people with type 1 diabetes access the education, technology, knowledge and urgent care they require. These issues are discussed in greater detail in the sections that follow. Overall approaches for people with newly diagnosed or established type 1 diabetes are shown in Figs 3 and 4.

AGP Report: Continuous Glucose Monitoring

Time in Ranges Goals for Type 1 and Type 2 Diabetes

Test Patient DOB: Jan 1, 1970

14 Days: August 8-August 21, 2021

Time CGM Active: 100%

Glucose Metrics

Average Glucose **175 mg/dL**
Goal: <154 mg/dL

Glucose Management Indicator (GMI) **7.5%**
Goal: <7%

Glucose Variability **45.5%**
Defined as percent coefficient of variation
Goal: ≤36%

Ambulatory Glucose Profile (AGP)

AGP is a summary of glucose values from the report period, with median (50%) and other percentiles shown as if they occurred in a single day.

Daily Glucose Profiles

Each daily profile represents a midnight-to-midnight period.

◀ **Fig. 2** CGM visualisation in an ambulatory glucose profile (AGP) report. Figure courtesy of R. M. Bergenstal and the International Diabetes Center, Minneapolis, MN, USA. To convert glucose values to mmol/l, values in mg/dl should be divided by 18. DOB, date of birth

Section 4: Schedule of care

A detailed evaluation should be obtained at the initial consultation, and more targeted interval care at follow-up visits with a focus on person-centred care (Table 2) [52, 53]. A personalised approach for visit frequency is recommended but visits should occur at least annually. More frequent contact, however, is preferred for most individuals, for example, those who have been recently diagnosed, those who are not meeting their diabetes goals, those who require cardiovascular risk management, and those who would benefit from additional self-management education and psychosocial support. The increased contact will allow additional review of glucose data and other support. Additional visits can also be useful when the therapeutic regimen changes, for example, when the insulin regimen is modified or when a new device is started.

In the past, initial and follow-up visits were primarily conducted face-to-face and telemedicine only used sporadically. With the onset of the coronavirus disease-2019 (COVID-19) pandemic, the use of telemedicine became a necessity and there was an abrupt widespread adoption of remote visits (videoconference/telephone call) to deliver diabetes care. Pre COVID-19, results from a limited number of studies using telemedicine in different subgroups of people with type 1 diabetes suggested that remote monitoring, education and provider visits have the potential to: improve outcomes, quality of life and self-management; increase access to care and reduce costs; and are well-accepted with improved treatment satisfaction [54–57].

The use of telemedicine, however, should be individualised and will vary depending upon individual needs, computer literacy and access to care [58]. The healthcare professional and person with diabetes should be in a private space. In advance of the visit, people with diabetes should receive clear instructions on the expectations for the televisit, including how to connect to the consultation and how to upload data from their diabetes devices (glucose meters, data-collecting applications [apps], CGM devices and insulin pumps) prior to the appointment [59]. When clinically indicated and appropriate, people with diabetes should be asked to weigh themselves and perform home blood pressure measurements where possible. A list of all medications and relevant medical reports should be available. Despite the value of telemedicine, people should have the option to schedule an in-person visit, where possible.

Section 5: Diabetes self-management education and support

DSMES is an essential component of type 1 diabetes care that allows all other diabetes interventions to work optimally. The objective of DSMES is to provide those living with type 1 diabetes (and their caregivers, if applicable) with the knowledge, skills and confidence to successfully self-manage the diabetes on a daily basis and, thereby, reduce the risks of acute and long-term complications while maintaining quality of life [60]. DSMES aims to empower people with type 1 diabetes, with an emphasis on shared decision-making and active collaboration with the healthcare team. Where possible, DSMES programmes should be evidence-based and conform to local and national standards to demonstrate effectiveness.

Levels and content of diabetes self-management education and support

Three levels of DSMES can be distinguished:

- Level 1 comprises provision of diabetes information and one-to-one advice.
- Level 2 refers to ongoing learning that may be informal, perhaps through a peer group.
- Level 3 DSMES refers to structured education that meets nationally agreed criteria, including an evidence-based curriculum, quality assurance of teaching standards and regular audit. These programmes are guided by learning and behaviour change theories.

Several Level 3 programmes have been developed for adults with type 1 diabetes and have proven to be effective, both in terms of improved glycaemic outcomes and improved psychosocial outcomes [61]. Most programmes use a group format, increasingly supplemented with digital support, including text messaging and cloud-based solutions and telemedicine [62]. Structured DSMES programmes most often include multiple components and cover a broad range of topics, from pathophysiology to medical technology and healthy coping (Table 3).

Specific DSMES should not be confined to one particular moment but offered on a continuous basis and tailored to the ever-evolving individual's educational needs. People with type 1 diabetes may be diagnosed at a young age or during adulthood, and many live with type 1 diabetes throughout different life stages. Four critical times where DSMES is particularly needed can be distinguished: (1) at diagnosis; (2) when not meeting targets; (3) when transitions occur; and (4) when complications develop (Fig. 5) [63]. DSMES should be revisited when a child transitions to adult diabetes services, as there may be significant knowledge gaps in someone diagnosed early in life, when education at the time was directed to the parents and caregivers. DSMES should be tailored towards an individual's needs, taking

Schematic for management of new-onset type 1 diabetes in an adult

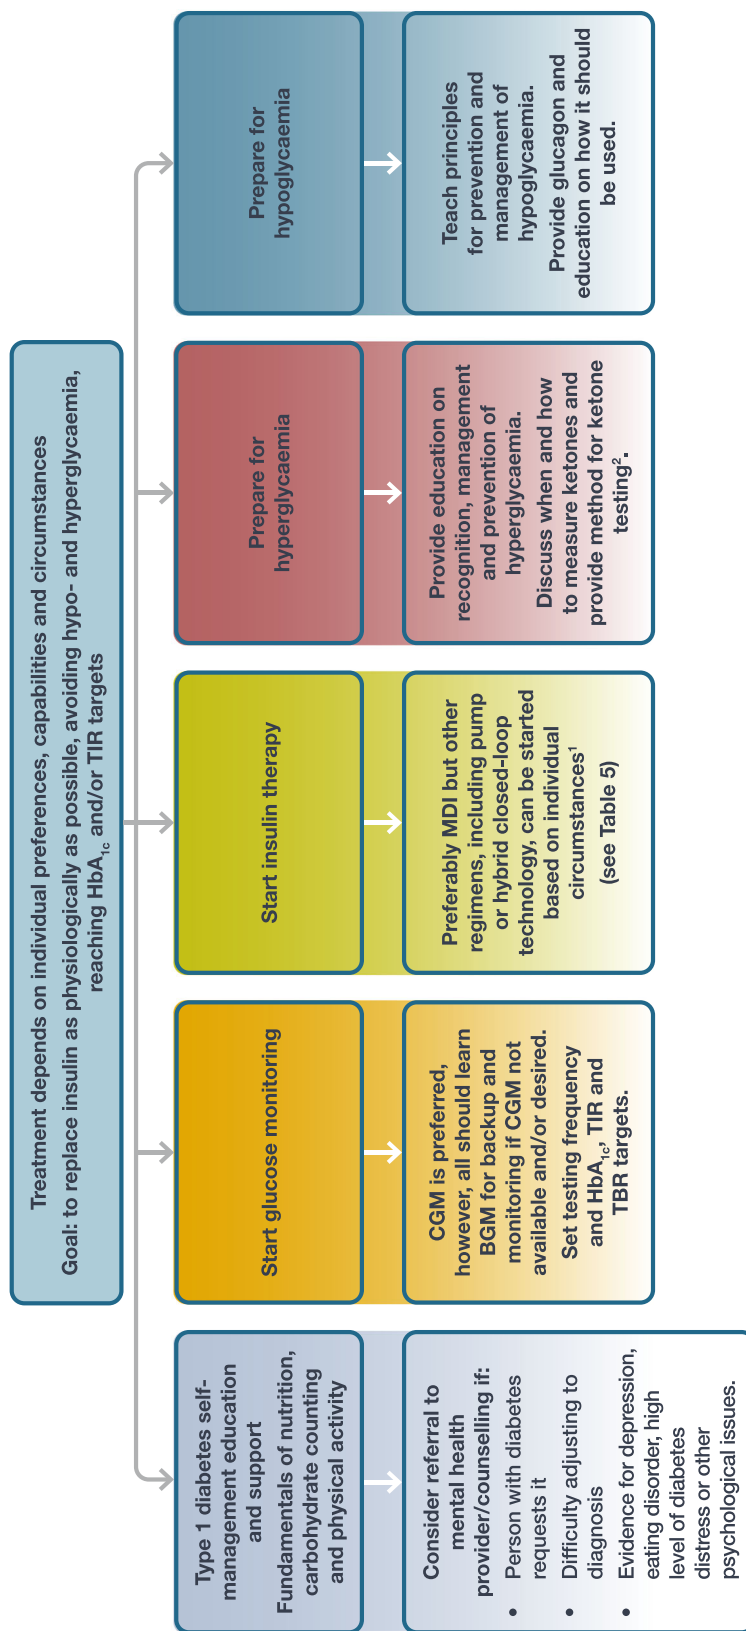

Fig. 3 A framework for initial assessment and treatment of an individual with newly diagnosed type 1 diabetes. In most people, frequent follow-up until the diabetes is stabilised is needed. ¹People can switch back and forth between MDI and pump or hybrid closed-loop therapy based on preference and circumstances; however, all people must be prepared to use injected insulin therapy if pump or hybrid closed-loop systems fail or are not available. ²The availability of blood and urine ketone measurement varies across healthcare systems

General principles for management of blood glucose in existing type 1 diabetes in an adult

into account cognitive function and literacy, family history and comorbidities, as well as ethnic, socio-cultural, financial, geographical and lifestyle factors [64]. A structured, periodic assessment of educational needs and barriers should be an integral part of ongoing diabetes care (see Text box: Needs assessment for diabetes management, education and support).

There are numerous smartphone and web-based apps that aim to help people with type 1 diabetes navigate the challenges of self-management. Although widely used, the available evidence on the safety and effectiveness of diabetes health apps remains limited, with issues ranging from inadequate evidence on app accuracy and clinical validity to lack of

Table 2 Schedule of care

Component of care	Details of evaluation
Medical and family history	
Diabetes history	Date of diagnosis Presentation at onset Islet autoantibodies (date) C-peptide (date) Episodes of DKA or Level 3 hypoglycaemia Hypoglycaemia awareness
Family history	Type 1 diabetes or type 2 diabetes in first-degree relatives Other autoimmune disorders
Personal history of chronic complications	Microvascular: retinopathy, macular oedema, laser/injection therapy, date of last retinal evaluation (exam or photos); peripheral neuropathy, autonomic neuropathy; nephropathy Macrovascular: heart, cerebrovascular and peripheral arterial disease
Personal history of common comorbidities	Foot ulcers or amputations Autoimmune disorders: thyroid, coeliac, others ^a Hypertension Lipid disorder Overweight and obesity Eating disorders Hearing loss Sleep disorder Dermopathy Fractures Joint and soft tissue disorders: cheiroarthropathy, trigger finger, capsulitis, carpal tunnel syndrome
Other	Dental and gum health Pregnancy and contraception history
Additional behavioural factors	Immunisation history Diet and nutrition: use of carbohydrate counting, weight history Physical activity Smoking, alcohol, substance use Sleep
Diabetes management	
Current insulin regimen	MDI: pens, including connected insulin pens; syringes; needles Insulin pump (type/model): settings; backup injection plan
BGM	Type of meter/strips Frequency of use Mean (SD), range
CGM	Pattern Type/model Data sharing; if yes, with whom Glucometrics
Other	Pattern Other diabetes medications Glucagon prescribed Ketone testing supplies prescribed (where available) Software/app use
Psychosocial issues	Monitor psychological wellbeing: diabetes-specific distress; depressive symptoms; anxiety symptoms Consider, also, the potential presence of fear of hypoglycaemia and disordered eating Screen for social determinants of health and social support
DSMES	Assess cognitive status Assess and plan for meeting individual needs

Table 2 (continued)

Component of care	Details of evaluation
Physical examination	<p>Consider contraception and pregnancy planning</p> <p>Height</p> <p>Weight, BMI: every visit</p> <p>Blood pressure and pulse: at least once a year</p> <p>Skin including injection/infusion sites: every visit if skin complaints or erratic glucose readings, otherwise annual</p> <p>Cardiovascular: annual; more often if previous abnormality or symptoms</p> <p>Feet: every visit if peripheral vascular disease, neuropathy, foot complaints or history of foot ulcer, otherwise annual</p>
Laboratory testing	<p>HbA_{1c} every 3–12 months</p> <p>Creatinine: annual; may be more often if kidney disease</p> <p>Urine albumin/creatinine ratio: annual</p> <p>Lipid panel: frequency dependent on the presence of previous lipid abnormality or treatment</p> <p>ALT and AST: at least once and as indicated clinically</p> <p>Serum potassium: if taking ACE-I, ARB or diuretic</p> <p>TSH, vitamin B₁₂, vitamin D, coeliac screen: at least once and as indicated clinically^a</p>
Goals setting	<p>Individualised, attainable, realistic: behavioural considerations (diet and nutrition, activity, smoking cessation)</p>
Treatment plan	<p>Glycaemic: HbA_{1c}, TIR, hypoglycaemia</p> <p>Formulate treatment plan with shared decision-making</p>
Referrals	<p>As needed: podiatry, cardiology, nephrology, ophthalmology, vascular surgery, gynaecology, others</p>

^a Individuals with type 1 diabetes are also at increased risk for the development of other autoimmune diseases, including autoimmune thyroid disorders, pernicious anaemia, coeliac disease, collagen vascular diseases and Addison's disease [291, 292]. The optimal frequency of screening for these conditions in adults has not been established

ACE-I, ACE inhibitor; ALT, alanine aminotransferase; ARB, angiotensin II receptor blocker; AST, aspartate aminotransferase; TSH, thyroid stimulating hormone

Needs assessment for diabetes management, education and support

- Health history
- Cognition, functional health literacy and numeracy
- Diabetes distress and support systems
- Religious and cultural influences
- Health beliefs and attitudes
- Physical limitations
- Social determinants of health e.g. financial status
- Barriers

training provision, poor interoperability and standardisation and insufficient data security [65].

Section 6: Monitoring of glucose levels

People with type 1 diabetes should have an assessment of their glucose levels with their healthcare professional as often as is clinically indicated, but at least annually. Glycaemic status should be assessed at least every 3 months in those whose therapy has changed or who are not meeting glycaemic goals.

HbA_{1c}

Monitoring of blood glucose has traditionally been by HbA_{1c}, which has been used in most studies that demonstrate the effects of lowering glucose on the development and progression of diabetes complications [39]. There is a strong correlation ($r = >0.9$) between HbA_{1c} and mean blood glucose levels during the preceding 3 months when glucose levels are stable [66]. In several conditions, however, HbA_{1c} does not reflect

Table 3 Key content areas of DSMES

Key content areas	Examples that focus on type 1 diabetes
Diabetes pathophysiology and treatment options	Immunology of beta cell destruction.
Healthy eating	Basic and advanced carbohydrate counting vs intuitive dosing. Impact of composition of meals (fat, protein, glycaemic index, fibre, sugar, alcohols) on glucose levels. Use of technology to enhance dosing recommendations.
Physical activity	Impact on glucose and insulin dose recommendations.
Medication usage	Types of available insulins. Methods of insulin delivery.
Monitoring and using patient-generated health data	Technology and its impact on the ability to have more frequent communication between the person with type 1 diabetes and their healthcare professional Reviewing CGM, pump and connected insulin pen downloads, and apps.
Preventing, detecting and treating acute complications (including hypoglycaemia, hyperglycaemia and DKA), sick day guidelines, and severe weather or situation crisis and diabetes supplies management	Euglycaemic DKA. DKA prevention with pump use. Glucagon use. Ketone testing.
Preventing, detecting and treating chronic complications, including immunisations and preventive eye, foot, dental and renal examinations, as indicated per the individual participant's duration of diabetes and health status	Understanding the individual risk for complications in type 1 diabetes. How to prevent development and progression of complications in the future.
Healthy coping with psychosocial issues and concerns	Discussing diabetes distress and burnout.
Problem solving	Goal setting. Developing personal strategies to promote health and behaviour change. Problem identification and solutions. Identifying and accessing resources. Sick day rules. Management of pump failure or pump holiday. Planning for procedures or surgery.

mean glucose; these are mainly situations where erythrocyte turnover is altered or in the presence of haemoglobinopathies (Table 4) [67]. Variability exists between individuals, but the HbA_{1c} and blood glucose within an individual correlate over time [68]. Although HbA_{1c} is an indicator of mean glucose, it does not inform glycaemic variability and hypoglycaemia and, therefore, is inappropriate as the only method of glucose evaluation in type 1 diabetes [68, 69].

Other biomarkers, such as fructosamine, 1,5-anhydroglucitol and glycated albumin, provide measures of mean glucose, albeit with shorter durations than HbA_{1c}. None of these are as well associated with diabetes complications as HbA_{1c} [70].

Capillary blood glucose monitoring

Capillary BGM involves the use of a handheld meter and provides a measurement of capillary plasma glucose.

Frequent BGM measurements are important as an integrated part of diabetes management to guide insulin dosage, food intake and prevention of hypoglycaemia with exercise. Every person with type 1 diabetes should have the equipment to undertake BGM, regardless of whether they are using CGM.

BGM is needed before meals to give the user the chance to adjust the meal insulin dose if the pre-meal glucose is out of range at the time, while measurements over a few days will show whether the doses active before that meal require adjustment. Additionally, BGM is needed to prevent and detect hypoglycaemia in several situations, such as: before bedtime; before driving; before, during, and after exercise; and when hypoglycaemic symptoms occur. The evidence for the optimal number of daily BGM measurements is lacking and may depend on variation in the person's lifestyle.

Four critical times for DSMES in type 1 diabetes

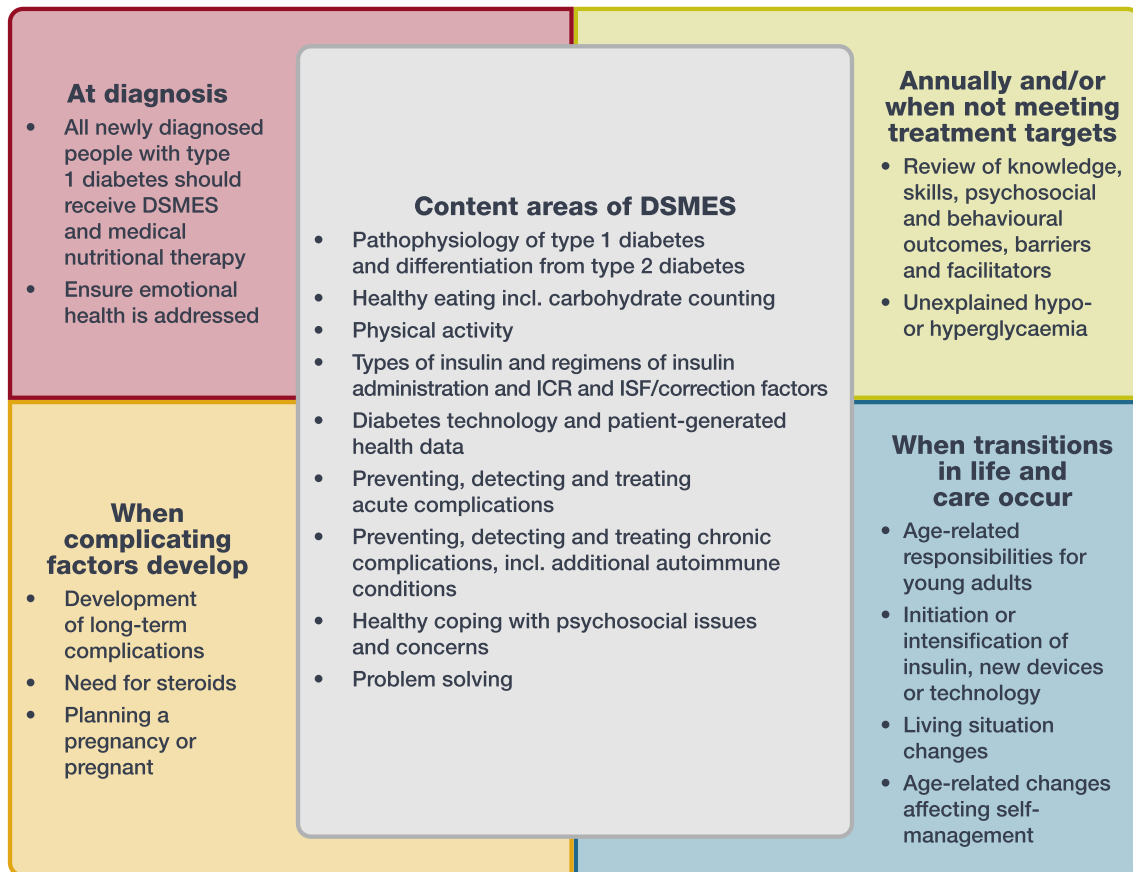

Fig. 5 The four critical times when DSMES is particularly needed for people with diabetes (and their caregivers, when applicable). ICR, insulin:carbohydrate ratio; incl., including; ISF, insulin sensitivity factor

In registry studies, increased testing frequency is associated with lower HbA_{1c} [71]. However, even with frequent BGM, most people with type 1 diabetes will have undetected and an unacceptable high frequency of hyper- and hypoglycaemia [72]. Frequent measurements are often not feasible and can be distressing. Seeing high or low glucose values can evoke feelings of frustration, anxiety and guilt, leading many people with type 1 diabetes to measure less often than needed [73]. Downloading memory-capable glucose meters can be helpful in observing patterns of hyper- or hypoglycaemia and allowing the person with diabetes to reflect on insulin dose adjustment [74]. Most meters meet the accuracy standards established by the International Organization for Standardization and manufacturers need to evaluate each product's clinical performance in a broad population of users over time to ensure that their products continue to meet standards of clinical accuracy [75].

Continuous glucose monitoring

CGM is the standard for glucose monitoring for most adults with type 1 diabetes. CGM devices, which have been available commercially since 2006, measure interstitial glucose to provide an estimate of plasma glucose. CGM devices have evolved and improved enough in accuracy to the point where most currently available sensors are 'non-adjunctive', meaning that a check with capillary BGM before a treatment decision is taken is not required. However, BGM may still be required if there are concerns that the CGM readings do not reflect the plasma glucose.

Currently there are two types of CGM devices: one provides a continuous value of current glucose and trends to a receiver, mobile app, smartwatch, or pump (designated as real-time CGM [rt-CGM]), while the other requires the glucose level to be determined by scanning a small reader or smartphone across the transmitter (intermittently scanned CGM [is-CGM]). Historically, rt-CGM has offered a variety of alerts, both in terms

Table 4 Non-glycaemic factors that alter HbA_{1c} levels [70]

Effect on HbA _{1c}	Factor
Apparent increase	<ul style="list-style-type: none"> • Age • Ethnicity: HbA_{1c} is slightly higher in African Americans than in people of White Northern-European ancestry^a • Anaemias with decreased erythrocyte turnover: iron, vitamin B₁₂, folate • Severe hypertriglyceridaemia (hypertriacylglycerolaemia) • Severe hyperbilirubinaemia • Chronic alcohol consumption • Chronic salicylate consumption • Chronic opioid ingestion
Apparent decrease	<ul style="list-style-type: none"> • Pregnancy (second and third trimester) • Anaemias of chronic disease • Haemolytic anaemia • Splenomegaly and splenectomy • Acute blood loss • Renal failure • Advanced liver disease drugs: dapsone; trimethoprim/sulfamethoxazole • Vitamin E ingestion • Ribavirin and interferon alpha • Erythrocyte transfusion
Apparent increase or decrease	<ul style="list-style-type: none"> • Haemoglobin variants • Vitamin C ingestion

^a Variability within races is greater than variability between races [293]

of indicating when a specific glucose level is reached as well as for trends in glucose levels. Early is-CGM devices did not have these alerts but increasingly include them. In the near future, these sensors and others in development will increasingly connect to other devices, including connected insulin pens. All currently available devices can be uploaded to an internet cloud to allow people with diabetes and healthcare professionals to easily view the data at or between clinic visits. CGMs report a reading every 1–15 min.

rt-CGM is effective for adults with type 1 diabetes in improving HbA_{1c} (particularly when high) and reducing hypoglycaemia for both those using insulin pumps or multiple daily injections (MDI) [42–44, 76]. RCTs of the original is-CGM devices are more mixed but observational data are supportive of their use. However, switching from is-CGM without alarms to rt-CGM improved TIR and HbA_{1c} and reduced Level 3 hypoglycaemia [77]. rt-CGM is beneficial in reducing the burden of hypoglycaemia in older adults with type 1 diabetes [78] and those with IAH [44]. Most people with type 1 diabetes can benefit from this technology with appropriate initial and ongoing education, including frequent observation of the glucose trends. The choice of the device should be based on individual preferences and circumstances.

Some people may not find CGM valuable as they may feel that they do not require it or find it stressful because they dislike being ‘attached to a device’, being constantly reminded

of their diabetes or feeling exhausted by alarms (alarm fatigue). Cost considerations can also play a role.

Retrospective analysis of CGM data can guide and enhance therapeutic decision-making, patient understanding and engagement in adjusting behaviours. Standardised glucose reports with visual cues, such as the ambulatory glucose profile (AGP) and daily tracings, should be available for all CGM devices (Text box: Standardised CGM metrics for clinical care; Fig. 2) [79, 80].

Although healthcare professionals should regularly access and review CGM data as part of clinical management, people with type 1 diabetes should be encouraged to review their own reports regularly and follow their progress over time, contacting their healthcare professional as needed for worsening or changing trends.

People with type 1 diabetes should be warned that contact dermatitis (both irritant and allergic) may occur with all CGM devices that attach to the skin [81–83]. In some instances, the use of an implanted sensor can help avoid skin reactions in those who are sensitive to tape [84, 85].

Ketone measurement

Ketone bodies are produced when insulin concentrations are too low to prevent lipolysis. If left untreated, ketosis can lead to progressive dehydration and DKA. Measurement of ketones is

Standardised CGM metrics for clinical care

- Number of days CGM device is worn:
 - recommend 14 days
- Percentage of time CGM device is active:
 - recommend 70% of data from 14 days
- Mean glucose
- GMI
- Glycaemic variability (%CV)
- Time above range
 - Per cent of readings and time >13.9 mmol/l (>250 mg/dl); Level 2 hyperglycaemia
 - Per cent of readings and time >10.0 mmol/l (>180 mg/dl); Level 1 and Level 2 hyperglycaemia
- TIR
 - Per cent of readings and TIR 3.9–10.0 mmol/l (70–180 mg/dl)
- TBR
 - Per cent of readings and time <3.9 mmol/l (<70 mg/dl); Level 1 and Level 2 hypoglycaemia
 - Per cent of readings and time <3.0 mmol/l (<54 mg/dl); Level 2 hypoglycaemia

important during periods of illness or hyperglycaemia to facilitate the management of the hyperglycaemia and prevent and/or treat DKA.

Ketone bodies may be measured in blood or urine. Urine testing, the traditional method, detects acetoacetate, but not β -hydroxybutyrate, which is measured in blood testing. This means that urine testing may give a falsely low estimate of ketosis. Furthermore, after an episode of ketoacidosis, measurement of blood ketones provides a more accurate assessment of adequate treatment as urine tests may continue to be positive for 48 h as acetone leaks from fat tissue after ketogenesis and lipolysis have stopped. Modern technology allows the rapid and accurate measurement of ketones from a finger prick blood sample using a strip and meter. Blood ketone measurement is the method of choice and so adults with type 1 diabetes should be offered blood ketone testing

strips and a meter [86]. Blood and urine ketone testing is not available in all countries and settings.

Section 7: Insulin therapy

The ideal regimen of insulin replacement maintains blood glucose in the normal physiological range, as far as possible, while allowing flexibility in terms of mealtimes and activity levels. Typical insulin replacement regimens incorporate several components: basal insulin to restrain gluconeogenesis and ketogenesis in the preprandial state; mealtime insulin to cover the intake of carbohydrate and other macronutrients; and correction insulin to treat hyperglycaemia.

Choice of regimen

Most people with type 1 diabetes should use regimens that mimic physiology as closely as possible, irrespective of the presentation. This is best achieved with either MDI of subcutaneous basal insulin analogues and mealtime rapid-acting or ultra-rapid-acting insulin analogues, or with continuous subcutaneous insulin infusion of a rapid-acting insulin analogue via a pump, delivered as continuous basal insulin combined with manual mealtime boluses. In the USA, inhaled human insulin is an alternative to subcutaneous rapid-acting analogues [3]. Although first-generation basal analogues and NPH insulin are frequently administered once a day, greater flexibility and better coverage of basal insulin needs may be obtained if they are administered twice daily. Trials have demonstrated that the latest basal analogues may cause less hypoglycaemia than first-generation basal analogues and NPH insulin, while rapid-acting analogues achieve better mealtime coverage and less post-meal hypoglycaemia than short-acting (regular) human insulin [87, 88]. Insulin analogues are, therefore, considered the insulins of choice.

Ultra-rapid analogues have a slightly earlier time of onset and peak action than rapid-acting analogues. These insulins reduce postprandial hyperglycaemia but have otherwise not been shown to reduce HbA_{1c} or hypoglycaemia to a greater extent than rapid-acting analogues [3]. Currently, recombinant human insulin or analogues of human insulin account for the vast majority of insulin used worldwide.

HbA_{1c}, TIR, and TBR are improved further when physiological MDI or pump regimens are augmented with CGM usage [89], with the greatest benefits seen with algorithm-driven automated basal (and in some systems correction) insulin delivery, which is commonly called hybrid closed-loop therapy [90, 91].

Despite these advantages, the costs of insulin analogues and CGM or pump therapy are barriers for some people, while others do not wish to wear a device or inject multiple times per day. In these cases, subcutaneous regimens of human short-

Representative relative attributes of insulin delivery approaches in people with type 1 diabetes¹

Injected insulin regimens	Flexibility	Lower risk of hypoglycaemia	Higher costs
MDI with LAA + RAA or URAA	+++	+++	+++
Less-preferred, alternative injected insulin regimens			
MDI with NPH + RAA or URAA	++	++	++
MDI with NPH + short-acting (regular) insulin	++	+	+
Two daily injections with NPH + short-acting (regular) insulin or premixed	+	+	+
Continuous insulin infusion regimens	Flexibility	Lower risk of hypoglycaemia	Higher costs
Hybrid closed-loop technology	+++++	+++++	+++++
Insulin pump with threshold/predictive low-glucose suspend	++++	++++	++++
Insulin pump therapy without automation	+++	+++	++++

Fig. 6 Choices of insulin regimens in people with type 1 diabetes. CGM improves outcomes with injected or infused insulin and is superior to BGM. Inhaled insulin may be used in place of injectable prandial insulin in the USA. ¹The number of plus signs (+) is an estimate of relative

association of the regimen with increased flexibility, lower risk of hypoglycaemia and higher costs between the considered regimens. LAA, long-acting insulin analogue; RAA, rapid-acting insulin analogue; URAA: ultra-rapid-acting insulin analogue

acting (regular) and NPH insulin or pre-mixed insulin, with BGM as frequently as feasible, may be used at a cost of higher glucose variability with higher risk of hypoglycaemia and less flexibility of lifestyle. Figure 6 shows advantages and disadvantages of more- or less-physiological insulin replacement regimens, while Table 5 provides details on various regimens that might be employed.

Mode of delivery

There are several options for the mode of insulin delivery and the choice of device should be individualised. Hybrid closed-loop systems are the most effective means of maintaining glucose in the normal range in people with type 1 diabetes [90, 91].

MDI therapy can be administered using vials and insulin syringes or insulin pens, with the latter providing more convenience with regard to dosing, but may be at higher cost.

Smaller gauge and shorter needles provide almost painless injections. Contrary to common wisdom, skin thickness is not significantly increased in individuals who have overweight or obesity. Needles as short as 4 mm, injected at a 90° angle, enter the subcutaneous space with minimal risk of intramuscular injection in most adults [92]. The use of longer needles increases the risk of intramuscular injection. MDI regimens may be enhanced with emerging technology, such as bolus calculators and memory-enabled pens that keep track of insulin doses.

Different insulin pumps for subcutaneous insulin delivery are available in many countries. The primary mechanical differences between pumps are whether they utilise external tubing to connect to an infusion set or a pod directly applied to the skin and controlled via a wireless connection to a controller. Current pumps include bolus calculators programmed with personalised insulin:carbohydrate ratio and correction factors.

Table 5 Examples of subcutaneous insulin regimens

Regimen	Timing and distribution	Advantages	Disadvantages	Adjusting doses
Regimens that more closely mimic normal insulin secretion				
Insulin pump therapy (hybrid closed-loop, low-glucose suspend, CGM-augmented open-loop, BGM-augmented open-loop)	Basal delivery of URAA or RAA; generally 40–60% of TDD. Mealtime and correction: URAA or RAA by bolus based on ICR and/or ISF and target glucose, with pre-meal insulin ~15 min before eating.	Can adjust basal rates for varying insulin sensitivity by time of day, for exercise and for sick days. Flexibility in meal timing and content. Pump can deliver insulin in increments of fractions of units. Potential for integration with CGM for low-glucose suspend or hybrid closed-loop. TIR % highest and TBR % lowest with hybrid closed-loop > low-glucose suspend > CGM-augmented open-loop > BGM-augmented open-loop. Can use pens for all components. Flexibility in meal timing and content. Insulin analogues cause less hypoglycaemia than human insulins.	Most expensive regimen. Must continuously wear one or more devices. Risk of rapid development of ketosis or DKA with interruption of insulin delivery. Potential reactions to adhesives and site infections. Most technically complex approach (harder for people with lower numeracy or literacy skills).	Mealtime insulin: if carbohydrate counting is accurate, change ICR if glucose after meal consistently out of target. Correction insulin: adjust ISF and/or target glucose if correction does not consistently bring glucose into range. Basal rates: adjust based on overnight, fasting or daytime glucose outside of activity of URAA/RAA bolus.
MDI: LAA+flexible doses of URAA or RAA at meals	LAA once daily (insulin detemir or insulin glargine may require twice-daily dosing); generally 50% of TDD. Mealtime and correction: URAA or RAA based on ICR and/or ISF and target glucose.		At least four daily injections. Most costly insulins. Smallest increment of insulin is 1 unit (0.5 unit with some pens). LAAs may not cover strong dawn phenomenon (rise in glucose in early morning hours) as well as pump therapy.	Mealtime insulin: if carbohydrate counting is accurate, change ICR if glucose after meal consistently out of target. Correction insulin: adjust ISF and/or target glucose if correction does not consistently bring glucose into range. LAA: based on overnight or fasting glucose or daytime glucose outside of activity time course, or URAA or RAA injections.
MDI regimens with less flexibility				
Four injections daily with fixed doses of N and RAA	Pre-breakfast: RAA ~20% of TDD. Pre-lunch: RAA ~10% of TDD. Pre-dinner: RAA ~10% of TDD. Bedtime: N ~50% of TDD.	May be feasible if unable to carbohydrate count. All meals have RAA coverage. N less expensive than LAAs.	Shorter duration RAA may lead to basal deficit during day; may need twice-daily N. Greater risk of nocturnal hypoglycaemia with N. Requires relatively consistent mealtimes and carbohydrate intake.	Pre-breakfast RAA: based on BGM after breakfast or before lunch. Pre-lunch RAA: based on BGM after lunch or before dinner. Pre-dinner RAA: based on BGM after dinner or at bedtime. Evening N: based on fasting or overnight BGM.
Four injections daily with fixed doses of N and R	Pre-breakfast: R ~20% of TDD. Pre-lunch: R ~10% of TDD. Pre-dinner: R ~10% of TDD. Bedtime: N ~50% of TDD.	May be feasible if unable to carbohydrate count. R can be dosed based on ICR and correction. All meals have R coverage. Least expensive insulins.	Greater risk of nocturnal hypoglycaemia with N. Greater risk of delayed post-meal hypoglycaemia with R. Requires relatively consistent mealtimes and carbohydrate intake. R must be injected at least 30 min before meal for better effect.	Pre-breakfast R: based on BGM after breakfast or before lunch. Pre-lunch R: based on BGM after lunch or before dinner. Pre-dinner R: based on BGM after dinner or at bedtime. Evening N: based on fasting or overnight BGM.

Table 5 (continued)

Regimen	Timing and distribution	Advantages	Disadvantages	Adjusting doses
Regimens with fewer daily injections				
Three injections daily: N+R or N+RAA	Pre-breakfast: ~40% N+~15% R or RAA. Pre-dinner: ~15% R or RAA. Bedtime: 30% N.	Morning insulins can be mixed in one syringe. May be appropriate for those who cannot take injection in middle of day. Morning N covers lunch to some extent. Same advantages of RAAs over R. Least (N+R) or less expensive insulins than MDI with analogues.	Greater risk of nocturnal hypoglycaemia with N than LAAs. Greater risk of delayed post-meal hypoglycaemia with R than RAAs. Requires relatively consistent mealtimes and carbohydrate intake. Coverage of post-lunch glucose often sub-optimal. R must be injected at least 30 min before meal for better effect.	Morning N: based on pre-dinner BGM. Morning R: based on pre-lunch BGM. Morning RAA: based on post-breakfast or pre-lunch BGM. Pre-dinner R: based on bedtime BGM. Pre-dinner RAA: based on post-dinner or bedtime BGM. Evening N: based on fasting BGM.
Twice-daily 'split-mixed': N+R or N+RAA	Pre-breakfast: ~40% N+~15% R or RAA. Pre-dinner: ~30% N+~15% R or RAA.	Least number of injections for people with strong preference for this. Insulins can be mixed in one syringe. Least (N+R) or less (N+RAA) expensive insulins vs analogues. Eliminates need for doses during the day.	Risk of hypoglycaemia in afternoon or middle of night from N. Fixed mealtimes and meal content. Coverage of post-lunch glucose often sub-optimal. Difficult to reach targets for blood glucose without hypoglycaemia.	Morning N: based on pre-dinner BGM. Morning R: based on pre-lunch BGM. Morning RAA: based on post-breakfast or pre-lunch BGM. Evening R: based on bedtime BGM. Evening RAA: based on post-dinner or bedtime BGM. Evening N: based on fasting BGM.

ICR, insulin:carbohydrate ratio; ISF, insulin sensitivity factor; LAA, long-acting analogue; N, NPH insulin; R, short-acting (regular) insulin; RAA: rapid-acting analogue; TDD, total daily insulin dose; URAA, ultra-rapid-acting analogue

Hybrid closed-loop systems comprise an insulin pump, continuous glucose sensor and a control algorithm. The algorithm controls basal insulin delivery and, in some cases, correction boluses, based on CGM data, while the user still boluses manually for meals [90, 91].

Some people with type 1 diabetes are using ‘do-it-yourself’, user-driven, open-source artificial insulin delivery systems, which use commercially available CGM systems and pumps, with software algorithms that communicate with both and can reverse-engineer the pump control of basal and corrective doses [93]. Regulatory bodies do not allow healthcare professionals to prescribe these systems, but healthcare professionals should respect an individual’s right to make informed choices about their care and continue to offer support to the people using these systems.

Fully closed-loop automated insulin delivery systems are currently being evaluated in clinical trials being conducted by several collaborative groups in both North America and Europe [94]. The expectation is that some of these will receive regulatory approval in the next few years. This should allow people with type 1 diabetes to achieve better glucose management with minimal risk of hypoglycaemia. Bi-hormonal (insulin and glucagon) automated insulin delivery systems are under investigation and could also contribute to the optimisation of glucose management. This is a rapidly evolving area, and readers may wish to keep abreast by referring to the ‘Technology’ section of the ADA Standards of Care, which is a living document that is updated frequently [53].

Adverse effects

The main adverse effect associated with insulin therapy is hypoglycaemia, which is discussed in the next section. The safety and efficacy of insulin therapy is closely related to glucose monitoring and insulin dose adjustments made by the individual with diabetes or, more recently, made automatically through control algorithms. Therefore, education in the management of insulin doses is a crucial component of this therapy, both at initiation and during follow-up. This education includes rescue strategies in case of hyperglycaemic or hypoglycaemic deviations, including the measurement of urine or blood ketone bodies or the prescription of carbohydrate intake and glucagon, respectively.

Insulin causes body weight gain and can lead to some people with type 1 diabetes reducing their insulin doses. Clinicians should review such weight concerns related to insulin and discuss strategies to avoid undesirable weight gain.

Skin reactions to subcutaneous insulin therapy include local inflammation (often due to the pH of or additives to the insulin), insulin-induced lipatrophy and insulin-induced lipohypertrophy. Lipatrophy has become rare as the purity of manufacture of human and analogue insulin has improved.

Lipohypertrophy is common and typically occurs when the same sites are repeatedly used for injections or pump sites; it leads to use of higher insulin doses and is a cause of glycaemic variability, leading to both hyper- and hypoglycaemia [95, 96]. People with type 1 diabetes should receive instructions about proper injection technique, including regular site rotation and skin examination, at the time of insulin initiation, with periodic reminders thereafter. Clinicians should inspect and palpate injection and infusion sites at least annually.

As described above for CGM devices, individuals should be warned about possible skin reactions to pump adhesives.

Alternative routes of administration

Although subcutaneous insulin therapy has been the mainstay of treatment for almost a century, this mode does not mimic physiological insulin secretion well. Healthy beta cells secrete a burst of insulin into the portal circulation at the onset of glucose intake, with approximately 70% of the insulin cleared by the liver and not entering the systemic circulation, whereas subcutaneous insulin enters the systemic circulation with some delay and is removed relatively slowly. Inhaled human insulin, available only in the USA, has a very rapid onset of action and short duration compared with subcutaneous rapid-acting analogues [3]. Inhaled insulin ameliorates early postprandial hyperglycaemia well, but its short duration of action results in less control of later postprandial hyperglycaemia. Additionally, inhaled insulin can cause cough or sore throat, and therapy must be monitored with periodic spirometry because of possible effects on lung function [97].

Peritoneal delivery of human short-acting (regular) insulin, with rapid transit to the portal system, can be accomplished with implantable insulin pumps or through a port connected to an intraperitoneal catheter (available only in some countries in Europe at considerable cost). Compared with subcutaneous insulin regimens, intraperitoneal insulin infusion reduces HbA_{1c}, glycaemic variability and hypoglycaemia [98, 99]. Insulin aggregation, local infections and catheter occlusions are reported complications of the devices used for this route of insulin delivery. In some individuals, an increased production of anti-insulin antibodies has been observed while using this route of insulin delivery. The effect on glucose levels is variable, ranging from no effect to marked glucose swings according to the binding affinity of the antibodies to insulin.

Section 8: Hypoglycaemia

Hypoglycaemia is the main limiting factor in the glycaemic management of type 1 diabetes. Hypoglycaemia is classified into three levels:

- Level 1 corresponds to a glucose value below 3.9 mmol/l (70 mg/dl) and greater than or equal to 3.0 mmol/l (54 mg/dl) and is named as an alert value.
- Level 2 is for glucose values below 3.0 mmol/l (54 mg/dl) and considered clinically important hypoglycaemia.
- Level 3 designates any hypoglycaemia characterised by altered mental state and/or physical status needing the intervention of a third party for recovery [100].

Although these were originally developed for clinical trials reporting, they are useful clinical constructs. Particular attention should be made to prevent Level 2 and 3 hypoglycaemia.

Level 1 hypoglycaemia is common, with most people with type 1 diabetes experiencing several episodes per week. Hypoglycaemia with glucose levels below 3.0 mmol/l (54 mg/dl) occurs much more often than previously appreciated [46, 101]. Level 3 hypoglycaemia is less common but occurred in 12% of adults with type 1 diabetes over a 6 month period in a recent global observational analysis [102]. Several studies have shown that rates of hypoglycaemia have not declined, even with more widespread use of insulin analogues and CGM, while other studies have shown benefit with these therapeutic advances [41].

Risks for hypoglycaemia, particularly Level 3 hypoglycaemia, include longer duration of diabetes, older age, history of recent Level 3 hypoglycaemia, alcohol ingestion, exercise, lower education levels, lower household incomes [41], chronic kidney disease and IAH [103–105]. Endocrine conditions, such as hypothyroidism, adrenal and growth hormone deficiency and coeliac disease may precipitate hypoglycaemia. Older diabetes databases consistently documented that people with lower HbA_{1c} levels had 2–3-fold higher rates of Level 3 hypoglycaemia. However, in the Type 1 Diabetes Exchange Clinic Registry, the risk of Level 3 hypoglycaemia was increased not only in those whose HbA_{1c} was below 7.0% (53 mmol/mol), but also in people with an HbA_{1c} above 7.5% (58 mmol/mol) [41].

It is possible that the absence of a relationship between HbA_{1c} and Level 3 hypoglycaemia in real-world settings is explained by relaxation of glycaemic targets by those with a history of hypoglycaemia, or confounders, such as inadequate self-management behaviours that contribute to both hyper- and hypoglycaemia. A secondary analysis of the IN CONTROL trial, where the primary analysis showed a reduction in Level 3 hypoglycaemia in people using CGM, demonstrated an increase in the rate of Level 3 hypoglycaemia with lower HbA_{1c}, similar to what was reported in the DCCT [106]. This implies that lowering HbA_{1c} may still come with a higher risk of Level 3 hypoglycaemia.

Mortality from hypoglycaemia in type 1 diabetes is not trivial. One recent trial noted more than 8% of deaths for those younger than 56 years were from hypoglycaemia [107]. The mechanism for this is complex, including cardiac arrhythmias, activation of both the coagulation system and inflammation

and endothelial dysfunction [108]. What may not be as well recognised is that Level 3 hypoglycaemia is also associated with major microvascular events, non-cardiovascular disease and death from any cause, although much of this evidence is obtained from people with type 2 diabetes [108]. With regard to cognitive function, in the DCCT and EDIC study, after 18 years of follow-up, severe hypoglycaemia in middle-aged adults did not appear to affect neurocognitive function [109]. However, independent of other risk factors and comorbidities, more episodes of severe hypoglycaemia were associated with greater decrements in psychomotor and mental efficiency that were most notable after 32 years of follow-up [110]. It appears that older adults with type 1 diabetes are more prone to mild cognitive impairment associated with hypoglycaemia [110, 111], while hypoglycaemia occurs more frequently in those with cognitive impairment. CGM data were not available in the DCCT era and so the true extent of serious hypoglycaemia over time is not known.

Impaired awareness of hypoglycaemia

IAH is the reduced ability to recognise low blood glucose levels that would otherwise prompt an appropriate corrective therapy [112]. Its prevalence is estimated to be close to 25% in people with type 1 diabetes but is likely to be underestimated according to CGM data [113]. IAH increases the risk of Level 3 hypoglycaemia by sixfold [114] and may lead to the person with diabetes omitting insulin injections intentionally or loosening tight glucose management to prevent their occurrence.

The pathophysiology of IAH is still not fully understood but includes a partial or total loss of sympathoadrenal reactions to hypoglycaemia that prevent catecholaminergic stimulation of hepatic glucose output and restraint of muscle glucose uptake [104]. The connections between autonomic neuropathy and IAH are complex since both the defect of sympathoadrenal reaction to hypoglycaemia can be a component of autonomic neuropathy and hypoglycaemia itself can promote neuropathy. Indeed, recurrent hypoglycaemia is a major cause of IAH. Sleep disturbance, psychological stress and alcohol can also induce IAH [112].

In clinical practice, physicians should be proactive in asking people with type 1 diabetes whether, and at which glucose level, they feel hypoglycaemia in order to identify IAH and adjust individual glucose targets to prevent the occurrence of Level 3 hypoglycaemia. The reference method to assess IAH is the hyperinsulinaemic–hypoglycaemic clamp [115], although this is not used out of a research frame due to its invasiveness, cost and time commitment from people with diabetes. Self-reported awareness, however, agrees well with the autonomic glucose threshold [116]. The Gold questionnaire and Clarke questionnaire, showing a score equal or above 4 are indicative of IAH [114, 117], and the Pedersen-Bjergaard et al questionnaire and Hypoglycaemia Awareness

Questionnaire (HypoA-Q) can also identify IAH [118, 119]. Another good test for hypoglycaemia awareness is to ask, ‘Do your symptoms of hypoglycaemia usually occur at a blood glucose level of ≥ 3.0 mmol/l (≥ 54 mg/dl) or < 3.0 mmol/l (< 54 mg/dl) or do you not feel symptoms?’ Those responding, ‘less than 3.0 mmol/l (54 mg/dl)’ or not experiencing symptoms have a >4 -fold increased risk of Level 3 hypoglycaemia [120]. The UK National Institute for Health and Care Excellence recommended for the first time that an assessment of hypoglycaemia, including awareness, should form part of clinical consultations [86].

Prevention of hypoglycaemia

Hypoglycaemia is not inevitable and several strategies can be used to reduce the risk [121]. Structured education programmes, such as Dose Adjustment For Normal Eating (DAFNE) and blood glucose awareness training (BGAT), which provide informed support for active insulin dose self-adjustment, are the key to the prevention of hypoglycaemia and lead to sustained falls in Level 3 hypoglycaemia rates in those at high risk [122, 123]. The use of insulin analogue regimens are associated with less hypoglycaemia, while hybrid closed-loop systems result in both improvement in TIR and reduction in TBR [91].

Strict avoidance of hypoglycaemia can help to restore hypoglycaemia awareness [124]. Structured diabetes education in flexible insulin therapy, which may incorporate psychotherapeutic and behavioural therapies, progressing to diabetes technology, incorporating sensors and insulin pumps, are effective treatments in those with persisting need [125]. CGM use promotes the identification of current or impending low glucose levels that people may not feel. BGAT, education to optimise insulin dosing and type, and hypoglycaemia avoidance motivational programmes all improve hypoglycaemia awareness. In some situations, it may be necessary to increase the glucose target range [124, 126]. Several clinical trials have not shown a reduction of IAH by using CGM despite a reduced incidence of Level 3 hypoglycaemia [101, 112, 124, 126–128].

Treatment of hypoglycaemia

The recommended correction of hypoglycaemia is the oral intake of approximately 15 g of glucose or equivalent simple carbohydrate when a capillary blood glucose level is < 3.9 mmol/l (< 70 mg/dl) [129]. This should be repeated every 15 min until any symptoms have resolved and the blood glucose level is above 3.9 mmol/l (70 mg/dl). A larger amount of glucose may be needed if glucose levels are below 3.0 mmol/l (54 mg/dl). Lower carbohydrate intakes can be used

when symptoms are associated with a capillary blood glucose level above 3.9 mmol/l (70 mg/dl). As there may be a 5–15 min lag between changes in capillary blood glucose and interstitial glucose, the restoration of normoglycaemia may not be detected by CGM straight away. The use of capillary glucose measurement is recommended to prevent over-treatment of the hypoglycaemia.

The specific recommendations for correction of hypoglycaemia or trends for hypoglycaemia according to CGM in people using automated insulin delivery systems will have to be defined as this mode of therapy expands in forthcoming years. Less carbohydrate (5–15 g) may need to be ingested to correct hypoglycaemia because the automated insulin delivery system should have already reduced or stopped basal insulin delivery [130].

Where there is a reduced level of consciousness, oral glucose intake is contraindicated because of risk for aspiration. Instead, glucagon via subcutaneous or intramuscular injection or nasal delivery should be given by attending people. Intravenous glucose injection is a possible alternative for healthcare professionals in cases of Level 3 hypoglycaemia.

After the acute symptoms have resolved, a further 20 g of long-acting carbohydrate as part of a snack or meal should be given and the cause of the hypoglycaemic episode sought to prevent further episodes.

Goal of nutrition therapy for type 1 diabetes

- Promote healthy eating patterns, emphasising a variety of nutrient-dense foods in appropriate sizes to improve overall health and to:
 - Improve HbA_{1c}, blood pressure and cholesterol and aid in maintaining weight
- Individualise nutrition needs based on personal and cultural preferences, health literacy and access to healthy food choices
- Provide practical tools for day-to-day meal planning
- Focus on matching insulin doses with meal composition through advanced carbohydrate counting

Information from [134].

Section 9: Additional behavioural considerations

Nutrition therapy

Nutrition, in particular carbohydrate intake, has a major effect on blood glucose levels, and people with type 1 diabetes need to understand the effect of food on their diabetes and plan meals accordingly (see Text box: Goal of nutrition therapy for type 1 diabetes). People with type 1 diabetes should be referred for individualised medical nutrition therapy provided by a registered dietitian who is knowledgeable and skilled in providing diabetes-specific nutritional advice in conjunction with the diabetes technology being used. Medical nutrition therapy delivered by a registered dietitian is associated with a reduction in HbA_{1c} of 1.0–1.9% (11–21 mmol/mol) for people with sub-optimally managed type 1 diabetes when integrated into an overall management programme [131].

There is no one eating pattern recommended for people with type 1 diabetes. The nutrition approach should be individualised based on personal preferences, socioeconomic status, cultural backgrounds and comorbidities. Carbohydrate counting is the most common meal planning approach in type 1 diabetes. In conjunction with promoting healthy eating patterns, carbohydrate counting and insulin:carbohydrate ratios can be a useful method for adjusting mealtime insulin dosing for optimal glycaemic outcomes [132, 133]. While low-carbohydrate and very-low-carbohydrate eating patterns have become increasingly popular and reduce HbA_{1c} levels in the short term, it is important to incorporate these in conjunction with healthy eating guidelines. Additional components of the meal, including high fat and/or high protein, may contribute to delayed hyperglycaemia and the need for insulin dose adjustments. Since this is highly variable between individuals, postprandial glucose measurements for up to 3 h or more may be needed to determine initial dose adjustments [134].

The average BMI of individuals with type 1 diabetes is rising at a faster rate than the general population, partly as a result of insulin intensification and societal factors that also affect the general population, such as physical inactivity. Weight loss and maintenance interventions involving nutritional advice and physical activity should be offered to individuals with type 1 diabetes who have overweight or obesity, in conjunction with other DSMES topics. New interactive technologies using mobile phones to provide information, insulin bolus calculations based on insulin:carbohydrate ratios and telemedicine communications with care providers may be used to aid in reducing both weight gain and the time required for education [65]. In the case of extreme low weight, unhealthy eating habits should be reviewed, including the possibility of insulin omission.

Alcohol and recreational drug use

Similar to the general population, many individuals with type 1 diabetes consume alcohol, although its effects on glycaemic management are not always adequately considered by those with diabetes and their healthcare professionals. Increased alcohol consumption is associated with a higher risk of DKA and Level 3 hypoglycaemia [135]. Some of this increase may occur through the association with other risk-taking behaviour. However, excessive alcohol consumption impairs cognitive function and symptom awareness, leading to a diminished ability to self-manage the diabetes. Alcohol promotes ketosis, which in the context of consumption of sugary alcoholic beverages, may increase the risk of DKA [136]. Alcohol also inhibits hepatic gluconeogenesis, leading to an increased risk of hypoglycaemia for up to 24 h after the last drink [137]. Hypoglycaemia is particularly hazardous because of the potential to confuse the symptoms of hypoglycaemia with alcohol intoxication.

Cannabis has been legalised in multiple jurisdictions. An association between recent recreational cannabis consumption and a more than twofold increased risk of DKA has been reported from countries where cannabis has been legalised, possibly related to the emergence of higher potency formulations of cannabis and other synthetic cannabinoids [138]. Use of cocaine and other stimulant-like drugs, such as amphetamine, methamphetamine and ecstasy (or 3,4-methylenedioxymethamphetamine [MDMA]), increase glucose production and inhibit glucose clearance, which increases the risk of DKA. Having a diagnosis of a substance use disorder confers an increased all-cause mortality in populations with diabetes across a range of substances, including cocaine, opioids and cannabis, regardless of consumption.

As many people are unlikely to spontaneously report their alcohol or drug use to clinicians, systematic screening for excess alcohol and/or drug use is recommended [139]. Healthcare professionals have a responsibility to inform people with type 1 diabetes about the effects of drugs and alcohol on diabetes and related risks, otherwise people with diabetes will seek information elsewhere, which is frequently incorrect and misleading [140]. Brief interventions to reduce risky drinking and drug use have been well validated in a variety of populations and offer the potential to improve diabetes medication taking and outcome [141]. In the case of alcohol or drug addiction, referral to a specialised clinic is warranted.

Smoking

Since smoking increases the risk of macrovascular and microvascular complications in people with diabetes, smoking cessation should be promoted and supported in all individuals with type 1 diabetes. The direct effect of smoking on blood

glucose levels in people with diabetes needs more research to assess the impact [142, 143].

Physical activity

People with type 1 diabetes should be encouraged to engage in a combination of aerobic and resistance exercise on most days because exercise is associated with improved fitness, increased insulin sensitivity, leading to reduced insulin requirement, improved cardiovascular health with better lipid profile and endothelial function, and decreased mortality [144–147]. Independent effects on beta cell function and HbA_{1c} have not been established beyond doubt but appear beneficial. In addition, regular physical activity is associated with reduced risk of microvascular complications, osteoporosis and cancer in people with type 1 diabetes [148]. Exercise also helps maintain a healthy BMI and promotes sleep quality and mental wellbeing.

It is important that physical activity is performed safely. The major risks are from the acute effects of exercise on glucose concentrations, which depend on several factors, including: the baseline fitness of the individual and type, intensity and the duration of activity; the amount of insulin in the circulation; the blood glucose concentration before exercise; and the composition of the last meal or snack. People with type 1 diabetes should be taught about the effects of exercise on glucose levels and how to balance exogenous insulin delivery and carbohydrate intake for the different forms and intensities of exercise.

Glycaemic management during exercise should be made safer with CGM systems. The updated consensus statement for management of exercise in type 1 diabetes highlights very detailed suggestions regarding the use of trend arrows and adjustment of insulin doses and carbohydrate intake [149].

When discussing the importance of exercise, consideration of cardiovascular and lower extremity comorbid conditions is critical. Advice should be given about appropriate footwear and foot inspection for those with peripheral neuropathy to avoid the risk of ulceration. However, walking does not increase the risk of ulceration in people with peripheral neuropathy [150]. Weight-bearing exercise should be avoided in active foot disease. If an individual has proliferative diabetic retinopathy or severe non-proliferative diabetic retinopathy, then vigorous activity requiring straining may be contraindicated because of the risk of vitreous haemorrhage or retinal detachment [151]. The individual should be advised to consult an ophthalmologist prior to engaging in an intense exercise regimen.

Additional details regarding the diabetes management during physical activity or exercise have been described elsewhere [152]. When there is excessive physical exercise combined with extreme low weight, an eating disorder should be considered.

Sleep

Proper sleep hygiene is essential for all individuals. Sleep may be disrupted in people with type 1 diabetes as a result of both behavioural and physiological aspects of diabetes and its management [153]. They may include hyper- and hypoglycaemic episodes, blood glucose variability and loss of blood pressure decline. However, studies performed so far have not determined causality. On the other hand, sleep disturbances including poor sleep quality and shorter sleep duration are associated with worsening glycaemic levels in type 1 diabetes [154, 155].

Sick day/illness management

Stressful events, including illness, may affect glucose levels and increase risk of DKA. More frequent glucose and ketone measurements are necessary to identify insulin adjustments. Individuals should devise a sick day management plan in consultation with their healthcare professional [156]. Examples of sick day protocols are available online [157, 158]. All recommend ingestion of adequate amounts of fluids and carbohydrates, as well as when to monitor glucose and ketone levels, give insulin and under what circumstances a person with diabetes should seek urgent medical care.

Driving

Unrecognised hypoglycaemia and rapidly dropping glucose levels are the most relevant hazards for drivers with type 1 diabetes. These risks may be reduced by the use of CGM or BGM prior to driving and at 2 hourly intervals. Local regulations and recommendations should be followed for driving with type 1 diabetes [159, 160]. In some countries, glucose meter downloads are essential to support applications for heavy goods and public service vehicle driving licenses. Safe driving practices should be discussed regularly with people who drive.

Employment

People with type 1 diabetes can successfully undertake a wide range of employment but there remains prejudice against those with diabetes that can limit employment opportunities. The main concerns are associated with the risks of acute hypoglycaemia as well as certain situations in which continued supply of effective insulin is not possible, for example working in very hot climates. Additionally, chronic diabetes complications may affect the ability to work in certain situations. For some occupations, any risk of hypoglycaemia is considered unacceptable, but efforts have been made to address these risks. For example, in some countries, people with type 1 diabetes are now working as commercial

airline pilots. For this reason, any person with type 1 diabetes should be supported to undertake professional activity, job or employment for which they are otherwise qualified and can do safely [161]. Employment circumstances should allow the safe use and storage of insulin and unrestrained access to glucose monitoring and self-treatment of hyper- or hypoglycaemia.

Travel

Planning ahead is the key to safe and trouble-free travel for individuals with type 1 diabetes. This includes preparing diabetes-related and emergency supplies, which should be available at hand during the travel. A plan of adjusting insulin doses, especially when travelling across time zones, is essential to reduce glucose fluctuations [162]. In particular, it is important to consider the impact of change in usual schedule, hot weather, reduced stress and relaxation, and changes in exercise patterns on glucose levels while on holiday.

Depending on the locale of travel destinations, it may be advisable to research the estimated carbohydrate content of local foods to aid better insulin adjustment. Frequent glucose measurement with CGM or BGM is advisable for any travel [163]. Additionally, it may be helpful to have note cards written in the local language to communicate that the person has type 1 diabetes and may need urgent glucose administration if hypoglycaemic.

Additional religious and cultural considerations

Fasting for religious and cultural reasons is a widespread practice globally. Healthcare professionals should ask if the person with type 1 diabetes wishes to partake in fasting and provide guidance and support [164].

Section 10: Psychosocial care

Type 1 diabetes is a psychologically challenging chronic condition, with treatment outcomes highly dependent on the person's ongoing self-care behaviours. Cognitive, emotional and social factors are critical determinants of self-care behaviours and, consequently, treatment success [165, 166]. Emotional health is an important focus and outcome of person-centred diabetes care [167].

Psychosocial problems

Diabetes-specific emotional distress affects 20–40% of people with type 1 diabetes and can be experienced at any point in time from early adulthood to older age. Two 'critical' times, however, are following the diagnosis and when complications develop [168]. Feeling powerless and overwhelmed by the

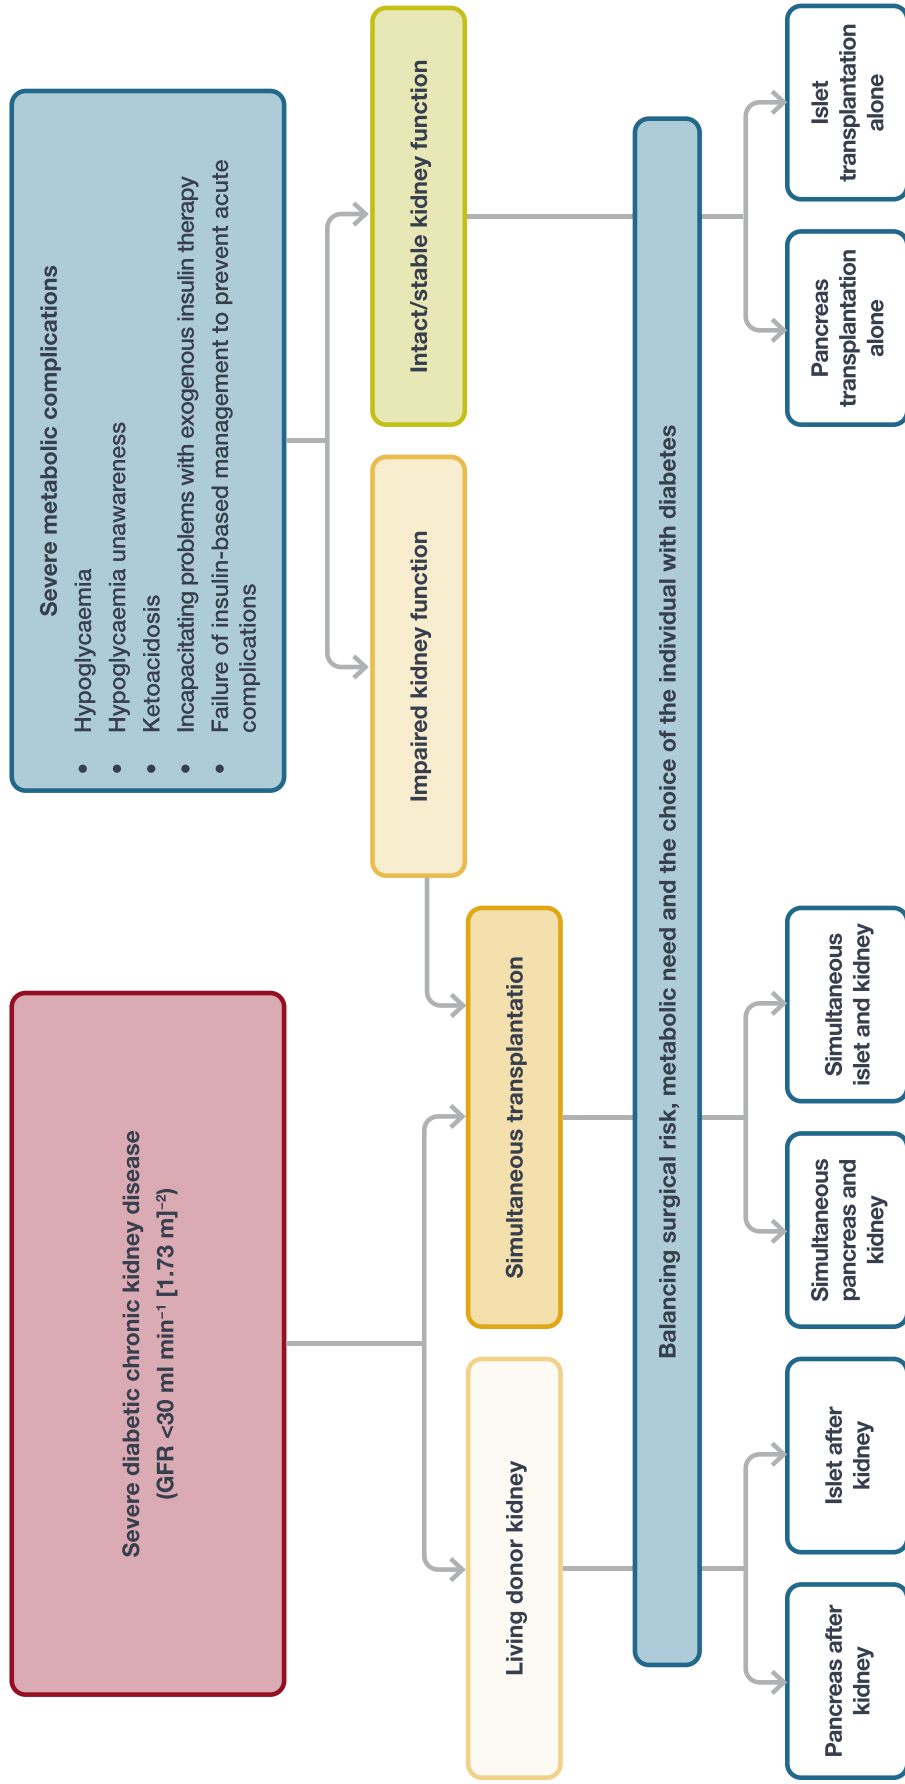

daily self-care demands, fear of hypoglycaemia and worries about complications are among the most cited sources of distress by people with type 1 diabetes. Prolonged significant diabetes distress is associated with depressed mood and elevated HbA_{1c} levels [169].

Lack of social support or feeling 'policed' by family, friends or co-workers also evokes emotional distress in individuals with type 1 diabetes [170]. Conversely, social support is a protective factor, serving as a buffer against stress. Depression and anxiety symptoms are twice as prevalent among people with type 1 diabetes relative to people without diabetes, negatively impacting quality of life [171–173]. Anxiety and depression often co-exist and may partly overlap with symptoms of diabetes distress [174]. Psychological distress, including mild to major depression, is a risk factor for poor self-care, hyperglycaemia, complications and excess mortality [174–176]. The association between generalised anxiety and sub-optimal blood glucose levels is less clear [177, 178].

Given the high prevalence and impact of psychosocial problems and psychological disorders in diabetes, screening and monitoring should be integral parts of diabetes care, not least because these psychological comorbidities tend to negatively affect diabetes outcomes and vice versa. Validated screening tools that can help to 'flag' psychological problems that may require follow-up or referral to a mental health specialist have been developed for most problem areas and are available in multiple languages. Clinicians engaging in screening need to understand the psychological and social issues that may complicate diabetes management, have good communication skills and be able to refer to specialised mental health services where appropriate. Recently, a working group from the International Consortium for Health Outcomes Measurement (ICHOM) made recommendations for a standard set of practical and validated psychosocial measures [179], including the WHO-5 Wellbeing Index (WHO-5) [180], Problem Areas in Diabetes (PAID) scale [181], and Patient Health Questionnaire (PHQ-9) [182]. Completion of these three questionnaires takes approximately 7 min and can be scheduled prior to the visit, either online or in the waiting room. For generalised anxiety, the Generalized Anxiety Disorder 7-item (GAD-7) is recommended [183]. Brief screeners for depression (two items) [184], depression and anxiety (four items) [185] and diabetes distress (five or two items) [186, 187] are also available.

Fig. 7 Simplified overview of indications for beta cell replacement therapy in people with type 1 diabetes. The two main forms of beta cell replacement therapy are whole-pancreas transplantation or islet cell transplantation. Beta cell replacement therapy can be combined with kidney transplantation if the individual has end-stage renal disease, which may be performed simultaneously or after kidney transplantation. All decisions about transplantation must balance the surgical risk, metabolic need and the choice of the individual with diabetes

Simplified overview of indications for beta cell replacement therapy in people with type 1 diabetes

Assessment and periodic monitoring of emotional health, at least on an annual basis, is recommended to promote case-finding, emotional wellbeing and patient satisfaction with care [188, 189]. This may require changes to current service provision, for example, inviting people with diabetes to complete standardised questionnaires prior to their consultation.

Fear of hypoglycaemia affects up to 10% of adults with type 1 diabetes, particularly among those experiencing repeated episodes of Level 3 hypoglycaemia [190]. Fear of hypoglycaemia may translate into avoidance behaviours aimed at keeping blood glucose at a 'safe' level, resulting in persistent hyperglycaemia [191]. In cases of problematic fear of hypoglycaemia, administering the Hypoglycemia Fear Survey (HFS) can help to identify specific worries and level of severity [192]. Both disproportional high and low fear of hypoglycaemia warrant attention.

Eating disorders, including anorexia nervosa, bulimia nervosa and binge eating, are over-represented in type 1 diabetes populations, particularly in young women [193, 194] but may also occur in men. Insulin omission as a weight-loss strategy ('diabulimia') often starting in teenage years warrants special attention [195, 196]. If indicated, screening for eating disorders is advised, using a validated instrument suited for use in people with type 1 diabetes, for example, the Diabetes Eating Problems Survey-Revised (DEPS-R) or Eating Disorders Inventory-3 Risk Composite (EDI-3RC) [197].

In case of a positive screen, offering a referral to specialised mental health services is recommended.

Social determinants of health

Social and financial hardships can negatively impact an individual's mental health, motivation, and capacity to engage in self-management practices, increasing the risk for elevated HbA_{1c} and complications. In a review of social determinants of health and diabetes [198], the importance of the following domains is discussed: (1) neighbourhood and physical environment (e.g. housing stability); (2) built environment (e.g. walkability, access to green spaces); (3) environmental exposures (e.g. pollution); (4) food access, availability and affordability; and (5) healthcare access, affordability and quality.

Socioeconomic challenges, particularly the inability to pay for food, insulin, other medications and supplies, need to be recognised and addressed. Several screening tools are available [199–204]. Sample questions that have been used include: How hard is it for you to pay for the very basics like food, housing, medical care, and heating? At any time since the last interview or in the last 2 years have you ended up taking less insulin than was prescribed for you because of cost? In the past 12 months has lack of transportation kept you from attending medical appointments or from getting insulin? The diabetes team should have access to a social

worker and/or links to community resources to help those with these needs.

Psychosocial interventions

All members of the diabetes care team have a responsibility for providing psychosocial care as an integral component of diabetes care. Preferably, the diabetes care team should include a mental health professional (psychiatrist, psychologist and/or social worker) to advise the team and consult with people with diabetes in need of psychosocial support [205]. Three levels of psychosocial support can be distinguished and diabetes teams have an important role in all three levels.

At the first level, people living with type 1 diabetes do not require professional mental health care. They may engage in self-help programmes and/or receive informal coaching, as well as family, peer and community support to assist them in coping with the psychological demands of self-managing type 1 diabetes as well as socioeconomic challenges. At the second level, which concerns approximately one-quarter of individuals with type 1 diabetes, some degree of professional psychosocial support is warranted. Support for social needs can be provided by a social worker and/or community organisation. It is important that therapists have a good understanding of diabetes treatments and integrate diabetes management in the psychological treatment. Psychological therapies, including time-limited (online) cognitive behavioural therapy (CBT), mindfulness and interpersonal therapies are effective with regard to a range of psychological outcomes, including diabetes distress and depression. The effects of psychotherapy on glycaemic levels are generally small but tend to increase when diabetes self-management education is incorporated in the treatment [206]. Approximately 5% of the adults with type 1 diabetes are in need of psychiatric treatment, the third level, which may involve psychotropic medication that can have an impact on glycaemic management. Psychiatric comorbidities, such as anorexia nervosa and schizophrenia, require close collaboration between the mental health specialist and diabetes care team [207, 208].

Section 11: Diabetic ketoacidosis

DKA is a life-threatening but preventable acute complication of type 1 diabetes, characterised by hyperglycaemia, metabolic acidosis and ketosis. There are times when the glucose levels are normal or only minimally elevated. The underlying cause is insulin deficiency, either absolute (new diagnosis of type 1 diabetes or omission of insulin in those with diagnosed disease) or relative (increased counter-regulatory hormones due to infection or other stressors without an adequate increase in insulin doses).

The prevalence of DKA and risk factors for the complication have been less-well studied in adults with type 1 diabetes than in children. In the USA, national surveillance of emergency department visits and hospital admissions suggests a rate of 28 cases per 1000 adults with diabetes per year, with a worrisome increase in emergency department visits and admissions for DKA seen since 2009 [209]. The US Type 1 Diabetes Exchange Clinic Network reported that 4.8% of participants (age 26 to 93 years) had been hospitalised for DKA in the prior year [41]. In a European (predominantly Germany and Austria) registry, adults with type 1 diabetes had DKA at a rate of 2.5 per 100 patient years [210].

As DKA occurs repeatedly in some people with diabetes, risk factors should be identified and approached in a prevention strategy. Some known risk factors are non-modifiable, such as low socioeconomic status, younger age, female sex and ethnicity [41, 210], whereas other factors associated with increased risk of DKA are potentially modifiable. These include having had one previous episode of DKA, high HbA_{1c}, low self-management skills (including omission of insulin therapy), psychiatric disorders, infections, somatic comorbidity, alcohol and drug abuse and less interaction with the healthcare team [211–213]. Older studies demonstrated a higher risk of DKA in those using insulin pumps, likely due to the lack of depot insulin when continuous delivery of insulin is disrupted [214]. However, more recent studies have not found this to be the case [41, 210, 215]. Adjunctive use of sodium–glucose cotransporter (SGLT) inhibitors (see below) in adults with type 1 diabetes increases the risk of DKA by an absolute rate of about 4% per year, suggesting the need for intensive diabetes self-management education and monitoring [216, 217]. DKA in the setting of SGLT inhibitor use is often so-called euglycaemic DKA, with initial case reports describing admission glucose levels of 5.3–12.4 mmol/l (96–224 mg/dl) [218].

Diabetes self-management education is an effective tool in reducing DKA risk. Additional medical, behavioural health interventions, including home ketone testing, and psychosocial support are often needed. Telemedicine offers the potential to reach populations with decreased access to care, and 24 h access to advice about managing hyperglycaemia and ketosis/ketonaemia at home can reduce the risk of hospital admission [211].

A detailed description of the management of DKA is beyond the scope of this report but the general principles of treatment are replacement of fluid, insulin and potassium. Different protocols for DKA treatment exist in different parts of the world [219, 220]. For further information regarding treatment, refer to previous reviews [221, 222].

Section 12: Pancreas and islet transplantation

Whole organ pancreas and pancreatic islet transplantation are currently the only means of clinical beta cell replacement (Fig.

7). Both therapeutic options can effectively prevent hypoglycaemia, restore normoglycaemia and possibly stabilise the progression of complications of type 1 diabetes [223–227]. However, chronic systemic immunosuppression is needed in both forms to prevent allogeneic rejection. Therefore, the indication must thoroughly balance risk and benefit, taking into consideration psychological factors as well [228]. In the USA, islet transplantation is not yet approved for clinical use and reimbursement.

Most whole-pancreas transplants are performed simultaneously with a kidney transplant (simultaneous pancreas and kidney [SPK] transplant). This is the ‘gold-standard’ therapy for people with type 1 diabetes and pre-final or end-stage renal disease if no contraindications (malignancies, chronic infections, insufficient self-management and severe cardiovascular conditions) are present. SPK transplants show a 5 year pancreas graft survival of 83% and are superior to pancreas transplants alone (PTA) or pancreas after a kidney transplant (55% and 70%, respectively) [229]. With an SPK transplant, most recipients can expect amelioration of problematic hypoglycaemia for more than a decade [229–231].

PTA are usually performed in people who are relatively young (<50 years) and do not have obesity (<30 kg/m²) or coronary artery disease. These selection criteria minimise operative mortality (<1%) and reduce early technical pancreas graft loss (<10%) [229, 232]. The main indications are a history of frequent, acute and severe metabolic complications (hypoglycaemia, hyperglycaemia, ketoacidosis), clinical and emotional problems with exogenous insulin therapy that are incapacitating, or consistent failure of insulin-based management, including technological aids [233].

Islet transplantation, a less invasive procedure, is indicated in people with excessive glycaemic lability and frequent Level 3 hypoglycaemia despite optimal medical therapy, and allows for inclusion of older people and those with coronary artery disease who would not be eligible for a whole-pancreas transplant [224, 234, 235]. Careful patient selection and protocol optimisation have led to substantial clinical improvements [224]. Insulin independence can be maintained for 5 years in 50% of recipients [236, 237]. Although achievement of insulin independence remains an important objective, several multi-centre clinical trials of islet transplants in people with type 1 diabetes and problematic hypoglycaemia have adopted a combination of near-normal glycaemic levels (HbA_{1c} <7.0% [<53 mmol/mol]) together with the elimination of Level 3 hypoglycaemia as the primary endpoint and the clinically relevant dual goal of intervention [238–240]. These outcomes can translate into improved patient-reported outcomes, but research in this area is limited [241].

Regardless of the beta cell replacement approach (pancreas or islets), the majority of recipients experience reliable prevention of problematic hypoglycaemia with near-normal glycaemic levels. Islet and pancreas transplants are the only approaches to date that

Table 6 Adjunctive therapies for type 1 diabetes

Variable	Metformin	Pramlintide	GLP-1 RA	SGLT-2 or SGLT-1/2 inhibitors
HbA _{1c} reduction	~1 mmol/mol (~0.1%)	3–4 mmol/mol (0.3–0.4%)	2–4 mmol/mol (0.2–0.4%)	2–4 mmol/mol (0.2–0.4%)
Fasting glucose	Minimal effect	No effect	Minimal effect	Modest decrease (0.8 mmol/l [15 mg/dl])
Postprandial glucose	Minimal effect	Significant decrease	Modest decrease	Modest decrease
TIR	No data	No data	No data	Increased (~12% at higher doses)
Insulin dose	Unchanged	Mealtime reductions	Predominantly mealtime reductions	Mealtime and basal reductions (~10% total reduction)
Body weight	Modest (~1 kg)	Modest (~1 kg)	Significant (~5 kg)	Moderate (2–3 kg)
Systolic blood pressure	No change	No change	4 mmHg decrease (with increase in heart rate)	3–4 mmHg decrease
Hypoglycaemia	Low risk	Potential increase in Level 3 hypoglycaemia if prandial insulin doses are not decreased	Increase in hypoglycaemia	Low risk
Side effects	GI side effects	GI side effects	GI side effects; increase in ketosis	Genital mycotic infections; increased risk of DKA
Approval status for type 1 diabetes in EU/US	Not currently approved	US approved	Not currently approved	EU approved low dose when BMI ≥ 27 kg/m ²
Specific groups for whom treatment may be of benefit	Women with polycystic ovary syndrome	No specific groups	Overweight and obese; high insulin dose; risk of cardiovascular and renal disease	Risk of cardiovascular and renal disease

EU, European Union; GI, gastrointestinal

confer both sustained recovery from IAH and restoration of glucose counter-regulation and, thereby, reliable protection from Level 3 hypoglycaemia in people with long-standing type 1 diabetes [242]. However, these approaches have not been compared with the newer systems of hybrid closed-loop technology, which might render immunosuppression requiring therapies less necessary, in large long-term studies [243].

Section 13: Adjunctive therapies

While insulin therapy is essential for people with type 1 diabetes, obtaining glycaemic goals with insulin alone is difficult because of the risks of hypoglycaemia. Furthermore, insulin therapy is often associated with undesirable weight gain, which may worsen insulin resistance, does not address other pathophysiological abnormalities, such as alpha cell dysfunction, and does not wholly protect individuals from an increased risk of cardiovascular disease or other complications. Adjunctive therapies aim to augment insulin therapy by addressing some of these critical unmet needs.

To date, although several drugs have been licensed as adjunctive therapies, the evidence of their effectiveness on clinically relevant outcomes other than blood glucose levels, such as cardiovascular and renal disease, is limited. It is not possible to make a general recommendation about their use but they can be considered in individual cases (Table 6). However, before these drugs are prescribed, insulin therapy should be optimised.

Metformin

Metformin has been evaluated in numerous small trials in people with type 1 diabetes with hopes that its insulin-sensitising properties would improve glycaemic management and/or reduce cardiovascular risk [244, 245]. The largest study to date assessed the use of metformin 1 g, twice daily, in 428 people with type 1 diabetes who were treated for 3 years, with a primary endpoint of changes in mean carotid intima-media thickness, a marker of cardiovascular disease risk. The study ultimately found no difference in the primary endpoint, minimal and non-sustained effects on HbA_{1c}, minimal effects on weight (~1 kg reduction) and no change in total daily insulin dose [246].

Pramlintide

Pramlintide, an amylin analogue, is approved for therapeutic use as an adjunctive therapy to insulin in the USA, but not in Europe. It remains the only US Food and Drug Administration (FDA)-approved adjunctive therapy for type 1 diabetes. Injection prior to meals acts to suppress glucagon secretion, delay gastric emptying and promote satiety [247–250]. Clinical trials have shown a reduction in HbA_{1c} (0.3–0.4% [3–4 mmol/mol]) and modest (~1 kg) weight loss [251–254]. As a result of its adverse effects and need for additional injections, clinical uptake of pramlintide has been limited. However, co-formulations of amylin with insulin are currently in development, as is the possibility of use of pramlintide in pumps or artificial pancreas systems.

Glucagon like peptide-1 receptor agonists

Glucagon like peptide-1 receptor agonists (GLP-1 RA) have been explored in people with type 1 diabetes for two indications; the first aimed to ameliorate beta cell decline at the time of diagnosis and there are ongoing trials of this approach. In one study of 308 people with recently diagnosed type 1 diabetes, liraglutide, when used in combination with anti-IL-21, preserved beta cell function [255]. The second indication is as an adjunctive therapy in established type 1 diabetes by blunting glucagon secretion, decreasing gastric emptying, and promoting satiety and weight loss [256]. The largest clinical trials in people with type 1 diabetes were conducted with liraglutide and showed decreases in HbA_{1c} at daily doses of 1.8 mg (0.2–0.4% [2–4 mmol/mol]), decreases in weight (~5 kg) and reductions in insulin doses [257, 258]. However, increased rates of hypoglycaemia and ketosis were shown. Subgroup analysis in people with residual C-peptide production suggests greater HbA_{1c} reduction and improved safety, with lower risk of ketosis. Trials in people with type 2 diabetes have shown convincing reductions in cardiovascular events with some GLP-1 RA [259]; whether these benefits would also be seen in people with type 1 diabetes is unknown. GLP-1 RA have been approved for management of obesity, but not in people with type 1 diabetes. However, given the clinical trial results in people without type 1 diabetes [260], these agents may have a role for those with type 1 diabetes who have concomitant obesity.

SGLT inhibitors

In several Phase III programmes in people with type 1 diabetes, the use of SGLT-1 or SGLT-1/2 inhibitors reduced HbA_{1c}, improved TIR, reduced body weight and improved blood pressure [244]. However, an increased rate of DKA led to rejection of market authorisation for type 1 diabetes by the FDA, whereas the European Medicines Agency has approved low-dose dapagliflozin (5 mg) and sotagliflozin (200 mg) for those with a BMI ≥ 27 kg/m² [261]. While no risk mitigation strategies have been proven to lower the risk of

DKA, a consensus statement on SGLT2 inhibitors and DKA suggested careful patient selection, appropriate insulin dose adjustment to avoid insulinopaenia, starting with a low dose of SGLT2 inhibitors, and regular ketone measurements with prompt action to address elevated values as sensible precautions aimed at preventing DKA [216].

In people with type 2 diabetes, improved cardiovascular outcomes, mainly due to a reduction in congestive heart failure, and improved renal outcomes have been established, but there are only limited data on the applicability of these findings to people with type 1 diabetes [262, 263]. However, increasingly, data on SGLT2 inhibitors have shown renal and heart failure benefits in people without diabetes, suggesting that people with type 1 diabetes and these comorbidities may also benefit.

Section 14: Special populations

Pregnancy including preconception and postnatal care

Both maternal and fetal pregnancy outcomes are worse in women with type 1 diabetes compared with women without diabetes. Hyperglycaemia before and during pregnancy increases the risk of complications in the pregnant woman and developing fetus and, also, affects further child development. Thus, women should be supported to achieve blood glucose ranges close to those seen in pregnant women without diabetes, with an HbA_{1c} target of 48 mmol/mol ($\leq 6.5\%$) [264, 265]. Women should aim for fasting and pre-meal glucose concentrations below 5.3 mmol/l (95 mg/dl), and postprandial values of below 7.8 mmol/l (140 mg/dl) 1 h after a meal and below 6.7 mmol/l (120 mg/dl) 2 h after a meal. Although CGM is not approved in the USA for use in pregnancy and no studies in pregnancy have used CGM alone, the Continuous Glucose Monitoring in Women With Type 1 Diabetes in Pregnancy Trial (CONCEPTT) showed that when CGM was used in conjunction with BGM, CGM was associated with better pregnancy outcomes [266] and is widely recommended in Europe. Many women rely on CGM during pregnancy and its use should be encouraged with the caveat that BGM should be performed if there are concerns that the CGM reading is inaccurate. When CGM is used in pregnancy, the target range is lower than outside of pregnancy (3.5–7.8 mmol/l [63–140 mg/dl]).

The major limiting step to achieving normoglycaemia is hypoglycaemia, which occurs more frequently in the first half of pregnancy, in part because of diminished awareness of hypoglycaemia and pregnancy-associated nausea and vomiting [267]. Pregnant women with type 1 diabetes are at risk of DKA at lower blood glucose levels than in the non-pregnant state and should receive education on DKA prevention and detection [268]. Postpartum breastfeeding, erratic sleep and eating schedules may increase the risk of

hypoglycaemia and insulin dosing may require adjustment [269, 270].

The management of pregnancy begins before conception as a planned pregnancy is associated with improved outcomes for both the women and offspring. Effective contraception should be used until the woman is ready for pregnancy. Choice of a safe and reliable method of contraception should be based on the preference of the woman, her individual risk factors, such as the presence of micro- or macrovascular complications, and the WHO Medical Eligibility Criteria for Contraceptive Use [271].

All women of childbearing age with type 1 diabetes should be informed about the importance of seeking professional help prior to trying to conceive; this provides an opportunity not only to improve glycaemic management but to offer folic acid to prevent neural tube defects, screen for diabetes-related complications and stop potentially teratogenic medications.

Diabetes in pregnancy is best managed by a multidisciplinary team, including a diabetologist/endocrinologist, obstetrician, dietitian, diabetes nurse/educator and diabetes midwife. A detailed description of the management of pregnancy in women with type 1 diabetes is beyond the scope of this report but is available elsewhere [272, 273].

Older people with type 1 diabetes

Insulin regimens in older adults should be individualised and patient safety is a key priority. Glycaemic targets should be based on functional status and life expectancy, rather than chronological age. As older adults with type 1 diabetes are especially vulnerable to hypoglycaemia, target glucose values should be adjusted to minimise the occurrence of hypoglycaemic events. Since, in some older adults with type 1 diabetes, administration of insulin may become more difficult, simplification of insulin management may be justified in cases of individuals with complications or functional or cognitive impairment. The use of advanced technologies in older individuals is useful and should not be discontinued or a priori excluded because of the older age [78, 274].

People with late complications of type 1 diabetes

As there is no evidence that intensive glycaemic management slows the progression of late microvascular complications of diabetes, glycaemic targets in individuals with advanced complications should be individualised and based on the balance of risks and benefits [39, 275]. Diabetes management may be particularly challenging in individuals with chronic kidney disease who may be at an increased risk of hypoglycaemia and in whom HbA_{1c} can be falsely low [276] and in people with gastroparesis and unpredictable rates of food absorption [277]. The rate of

optimising blood glucose levels in this group of people should also be individualised as rapid improvement may be associated with transient early worsening of retinopathy or the development of acute painful neuropathy [278, 279]. In people with cardiovascular complications, hypoglycaemia avoidance should be one of the management priorities [280].

Section 15: Inpatient management of type 1 diabetes

There have been no large RCTs specifically assessing glycaemic targets for inpatients with type 1 diabetes. Therefore, type 2 diabetes guidelines should be followed, which recommend target glucose ranges of 7.8–10.0 mmol/l (140–180 mg/dl) for the majority of non-critically and critically ill patients [281]. However, it is important that the healthcare team recognises key differences between type 1 diabetes and type 2 diabetes. People with type 1 diabetes, particularly those with concomitant chronic kidney disease, are at higher risk of hypoglycaemia, which should be avoided by careful insulin and carbohydrate matching [129]. Furthermore, people with type 1 diabetes are at high risk of developing ketosis if insulin is withheld [282]. People with type 1 diabetes often find the inpatient care of their diabetes stressful and disempowering. A major issue for some inpatients with type 1 diabetes care is coping with fixed meal timings. Therefore, inpatients with type 1 diabetes should be clearly identified to avoid common errors, such as omission of mealtime insulin or withholding of basal insulin for procedures or surgery.

Inpatient services should have protocols to allow people who can monitor their glucose and self-administer insulin safely to do so. Similarly, patients using diabetes devices should be allowed to use them in an inpatient setting or during outpatient procedures when proper supervision is available and the patient/caregiver is capable of managing the device(s) [283]. Whenever a dedicated inpatient diabetes service is available, they should be consulted for glycaemic management, DSMES and discharge planning [284]. Finally, the use of diabetes technology (CGM and insulin pumps) can be continued in selected, non-critically ill patients with clear mentation and previous training and education [285, 286]. Institutions should develop clear guidelines to manage inpatient type 1 diabetes safely.

Section 16: Emergent and future perspectives

Both xenotransplantation with porcine islets and human stem cells are under investigation to solve the problem of limited availability of donors for pancreas or islet transplantation [287].

Stem cell strategies have used either patient-specific stem cells or universal allogeneic cells. In the former, the patient's own stem cells are reprogrammed or transdifferentiated to become beta cells. By contrast, generic allogeneic cells may be used for multiple patients and centrally produced from a bank of human embryonic stem cells (hESCs) or of induced pluripotent stem cells (iPSCs). One of the key issues is protecting the cells from immune attack, both rejection and recurrent autoimmunity. Three general strategies are being investigated: (1) use of immunosuppressive or immunomodulatory drugs; (2) use of a physical barrier (e.g. encapsulation) [288]; and (3) gene editing for immune evasion and/or immune protection [289]. Both academic and commercial groups are pursuing these approaches and some are already in clinical trials.

Immunotherapy approaches are being evaluated for their potential use in Stage 1 (≥ 2 islet autoantibodies but normoglycaemia) or Stage 2 (autoantibodies and dysglycaemia) type 1 diabetes to prevent Stage 3 clinical type 1 diabetes, and for the preservation of beta cell function before and shortly after onset of Stage 3 clinical type 1 diabetes [290]. Many interventions have been tested in clinical trials but, to date, the most promising results have been from the anti-CD3 monoclonal antibody teplizumab, low-dose anti-thymocyte globulin (ATG), and the anti-TNF drug, golimumab. These have been shown to preserve beta cell function in recent-onset type 1 diabetes, and teplizumab also has delayed the clinical onset of type 1 diabetes. Several other trials are underway with the hope of not only preserving but even improving beta cell function and being able to interdict the type 1 diabetes disease process sufficiently to prevent the development of the disease.

Section 17: Conclusion

This report has covered many areas of the management of type 1 diabetes, however, the writing group recognises that huge gaps exist in our knowledge in the prevention, diagnosis and treatment of the disease. People with type 1 diabetes deserve better, higher quality research evidence on which to determine their optimal care. We are also aware of the inequalities in treatment experienced by many people with type 1 diabetes and we must advocate for better services to ensure that all individuals with type 1 diabetes have access to the care they need.

Behavioural Research in Diabetes, Melbourne, VIC, Australia), A.-G. Ziegler (Technical University of Munich, Munich, Germany) and C. Mathieu (Katholieke Universiteit Leuven, Leuven, Belgium) for serving as internal peer reviewers for the EASD and ADA. We would like to thank C. Franklin and M. Bonar of the Leicester Diabetes Centre (Leicester, UK) for the graphic design of the figures and R. M. Bergenstal and the International Diabetes Center, Minneapolis (MN, USA) for the ambulatory glucose profile (AGP) figure (Fig. 2).

Funding The report was jointly commissioned and funded by the ADA and EASD. The authors did not receive any payment for their involvement in the writing group.

Authors' relationships and activities RIGH serves on the speakers' bureau for and receives research support from Novo Nordisk. He serves on the speakers' bureau for Abbott, Eli Lilly, Otsuka and Roche. He also served as the Editor-in-Chief of *Diabetic Medicine* until December 2020. JHD received research funding from Afon, Eli Lilly and Novo Nordisk. He served on advisory boards for Adocia, Novo Nordisk and Zealand Pharma and was on a speaker's bureau for Novo Nordisk. AH-F is an auditor for the ADA's Education Recognition Program. She is a participant in a speaker's bureau for Abbott Diabetes Care and Xeris. She is also a member of Xeris' advisory board. IBH receives industry research funding from Medtronic Diabetes, Insulet and Beta Bionics. He is a consultant for Bigfoot, Roche and Abbott Diabetes Care. MSK receives research funding from Novo Nordisk and Bayer. TK has served on advisory boards for Abbott, Ascensia, Bioton, Boehringer Ingelheim, Dexcom, Eli Lilly, Medtronic, Roche, Sanofi and Ypsomed. He has received research funding from Medtronic and is a participant in a speakers' bureau for Abbott, Ascensia, Bioton, Boehringer Ingelheim, Eli Lilly, Medtronic, Novo Nordisk, Roche, Sanofi and Servier. BL declares that there are no relationships or activities that might bias, or be perceived to bias, their work. KN receives research funding from, is a member of the advisory board for, and is a stockholder in Novo Nordisk. She is an advisory board member for Medtronic and Abbott Diabetes Care and receives research funding from Dexcom, Medtronic and Zealand Pharma. JP is a consultant to Sanofi, Novo Nordisk, Eli Lilly, Zealand, Mannkind and Diasome. ER serves on the advisory board for Abbott, Air Liquide SI, Dexcom, Insulet, Sanofi, Roche, Novo Nordisk and Eli Lilly, and received research support from Dexcom and Tandem. JSS is a member of the board of directors for Applied Therapeutics and Dexcom. He serves on the scientific advisory board for Abvance, ActoBiotics, Adocia, Avotres, Oramed, Orgenesis, Sanofi Diabetes, Tolerion and Viacyte. He received research support from Tolerion. He is an advisor and consultant to Boehringer Ingelheim, Dance Biopharm/Aerami Therapeutics, Entera, Ideal Life, Incyse, Immunomolecular Therapeutics, Novo Nordisk, Provention Bio, Sanofi Diabetes, Signos, Tolerion and VielaBio. He is a shareholder or option holder in Abvance, Avotres, Dance Biopharm/Aerami Therapeutics, Dexcom, Ideal Life, Immunomolecular Therapeutics, Oramed and Orgenesis. FJS is consultant to Abbott, Eli Lilly, Sanofi and Novo Nordisk, and serves on the speakers' bureau for Abbott, Eli Lilly, Sanofi and Novo Nordisk. He has received research funding from Sanofi and Novo Nordisk. RSW receives research funding from Eli Lilly, Medtronic, Insulet, Diasome, Kowa, Tolerion, Novo Nordisk and Boehringer Ingelheim. ALP serves on the advisory board for Abbott Diabetes Care, Eli Lilly, Novo Nordisk, Medscape and Zealand Pharmaceuticals. She has received research support from Dexcom and Insulet and has received donated devices from Abbott Diabetes Care. She also has stock options from Omada Health and Livongo and is a special government employee of the FDA.

Contribution statement RIGH and ALP were co-chairs for the consensus statement writing group. AH-F, IBH, MSK, JP, JSS and RSW were the writing group members for the ADA. JHD, TK, BL, KN, ER and FJS were the writing group members for the EASD. All authors were responsible for drafting the article and revising it critically for important intellectual content. All authors approved the version to be published.
